In general investigations, the factors most consistently associated with an increased incidence of postoperative infection are age over 60 years, long preoperative stay in hospital, long duration of operation, pre-existing infection at the site of the wound, and bacteria in the wound at the end of the operation. Underlying disease, such as diabetes, immunosuppression or irradiation, and in some studies, malnutrition and administration of adrenocorticosteroids, are also important. In preoperative preparation, shaving of hair from the site, rather than treatment with depilatories or clipping, has been associated with a much greater frequency of infection (Seropian and Reynolds 1971), but other aspects of skin preparation

appeared not to exert a consistent effect. Factors of significance in some studies but not in others are male sex, emergency operations, and the use of surgical drains. It is generally agreed that good surgical technique is most important, but it is difficult to single out particular surgical practices. The use of diathermy was associated with increased infection in one series (Cruse and Foord 1973).

Overall, *S. aureus* is the dominant species in SSI, followed by the enterobacteria (Meers et al. 1981). UK surveillance data show that approximately two-thirds of *S. aureus* SSIs are caused by MRSA. Even higher MRSA prevalence in SSIs is seen in subspecialities such as vascular surgery (Public Health Laboratory Service 2002). Sternal wound infection after cardiac surgery, though difficult to recognize clinically in the early stages, may later be associated with mediastinitis, osteomyelitis, septicemia, and colonization of prosthetic material, and thus with significant morbidity and mortality. Infection occurs at the time of operation from the many sources outlined above; it is probable that a relatively small inoculum is needed in the inevitably damaged tissue. Prevention may be a major role for the prophylactic antibiotics that are used almost universally in cardiac surgery (Farrington 1986). Among factors that have been cited as predisposing to this type of postoperative infection are long and double procedures, excessive trauma to the sternum, postoperative hematoma formation, and reopening of the wound (Sarr et al. 1984), as well as the features already described as predisposing to surgical wound infection in general. It has been reported that the incidence of infection is greater in coronary artery bypass surgery when leg veins are used, and that the infecting organisms, particularly gram-negative bacilli, may be transferred from the leg. Infection of the leg wound itself is also common (Wells et al. 1983; Farrington et al. 1985).

The microbiological findings vary with the site and type of operation and also with the adequacy of culture methods, which often underestimate the role of anaerobic bacteria, such as *Bacteroides* spp. These, with other gut bacteria, often in mixed growth, are typical of infections after a colonized viscus is entered (Dunn and Simmons 1984). *S. aureus* may occur in all types of wound and is the typical cause of the less frequent wound infection in 'clean' surgery. Most infection of surgical wounds occurs at the time of operation. Evidence from animal experiments (Burke 1961) and studies of the effectiveness of antibiotic prophylaxis (e.g. Stone et al. 1976) suggest that there is a short period after bacterial contamination during which infection is initiated. In the great majority of cases, the origin of the bacteria appears to be the patient's own body flora. Much less often it is from a member of the operating team, but in many instances the origin is obscure. Occasionally a cluster of infections can be related to an organism present in a septic lesion or at a carrier site in a member of the operating team, but this is uncommon. The route by which a patient becomes infected is often not clear. The air-borne route is important in the implantation of prostheses, and in rare episodes in general surgery, which were linked with an identifiable source among the theater staff, the circumstances strongly suggested the air as the vehicle. More usual routes are direct spread from incised organs, and intraoperative contamination of instruments and of surgeons' gloves and clothing. Contamination from apparatus such as that providing an extracorporeal circulation has occasionally been described.

BURNS

Burns provide a suitable site for bacterial multiplication. When this has taken place, the burn is a richer and more persistent source of infection than the surgical wound because a larger area of tissue is exposed for a longer time. The clinical consequences of infection in burns may be very serious; a large proportion of the mortality in burned patients who have survived the initial trauma and shock has been due to infection. Multiple-antibiotic resistance in the infecting agents has for many years presented difficulties in the treatment of burned patients.

S. aureus and *P. aeruginosa* are the most common isolates in most burns units, followed by various enterobacteria and other gram-negative bacilli, such as *Acinetobacter* species *S. pyogenes*, once a cause of serious trouble in burns units (Cruickshank 1935), now colonizes comparatively few patients (Lawrence 1985). Nevertheless, *S. pyogenes* is important both in episodes of acute infection and in causing the failure of skin grafts. As in other hospital areas, the emergence of resistant gram-positive bacteria, including multiresistant enterococci and *S. aureus*, has been seen in burns units (Phillips et al. 1992; Donati et al. 1993).

As in many other sites, colonization without invasion is far more common than invasive infection, but the frequency and clinical severity of septicemic infections caused by most of the potential pathogens, particularly by *P. aeruginosa*, encourage regular monitoring by the culture of swabs from burns. A greater understanding of the relationship between the bacteria present and the host tissues can be obtained by examining punch biopsies (Pruitt and McManus 1992). Septicemia may follow surgical intervention; this may be prevented by systemic antibiotic prophylaxis, as is applied in most burns units (Papini et al. 1995).

Bacteria reach burns mainly by indirect contact. Airborne infection has been demonstrated on occasions and is more important for *S. aureus* than for gram-negative bacilli. Occasionally mattresses, baths, and hydrotherapy pools have been incriminated (Ayliffe and Lilly 1985; Tredget et al. 1992). In some studies, standard infection control measures, including controlled ventilation, have

not been shown to greatly influence the colonization of burns by bacteria, including antibiotic-resistant strains (Ayliffe and Lawrence 1985), although it has been suggested that single-room isolation reduces the problem of infection by gram-negative bacilli (Pruitt and McManus 1992; McManus et al. 1994). It is clear that improvements in the surgical management of burns, including judicious use of excision and timely closure, and the use of topical chemotherapy with agents such as silver sulfadiazine, have considerably reduced infection in many units.

Infection associated with extensive skin disease and major plastic surgery presents problems that are to some extent similar to those with burns.

THE EYE

The cornea is considered sterile, but the conjunctiva is colonized by a number of different bacterial genera, predominantly coagulase-negative staphylococci, *Corynebacterium* spp., and *Propionibacterium* spp. (Willcox and Stapleton 1996). Resident flora and other physiological factors, e.g. immunoglobulins in tears, prevent colonization by more pathogenic bacteria. The use of contact lenses is associated with colonization by *S. aureus* and gram-negative bacilli. Postoperative infections of the eye are uncommon, but may result in considerable disability and are difficult to treat. An etiological diagnosis is usually possible only if material for culture is obtained from within the eye. Preoperative monitoring of the eye flora is not usually indicated unless there are clinical signs of infection on the surface of the eye. It may, however, be useful to examine swabs from the skin round the eye and from the anterior nares for *S. aureus*, particularly if the patient has a skin disease, so that extra care can be taken with skin preparation if *S. aureus* are recovered.

Endophthalmitis is an infection of the intraocular structures and sclera and usually occurs following intraocular surgery or penetrating trauma, or as part of a generalized infection, such as systemic candidiasis. Infection after cataract surgery has declined in recent years and is now less than 0.1 percent (Das and Symonds 1996). Gram-positive bacteria predominate; a survey of 64 centers in France identified *S. epidermidis* as the most important pathogen (Fisch et al. 1991). A similar finding was reported in a UK study (Hassan et al. 1992). The somewhat surprising emergence of *S. epidermidis*, traditionally associated with the immunocompromised host and with foreign body-related infection, may represent improved diagnostic techniques. Various fungi cause occasional infections, presumably by the air-borne route. Many donor corneas yield microbial growth, but few patients develop infection with organisms similar to those found on the cornea. The importance of making a microbiological diagnosis should not be underestimated as management is difficult, partly because antimicrobial agents penetrate poorly into the anterior and vitreous chambers of the eye.

Keratoconjunctivitis is usually community-acquired and is most commonly caused by *S. aureus*, but *P. aeruginosa* may be associated with corneal ulceration in hospital and *Haemophilus influenzae* with infection in children (Limberg 1991). Epidemics caused by adenovirus type 8 are essentially an infection of hospitals and clinics, possibly spread by instruments such as tonometers, but also by the hands of staff, and otherwise only by close, person-to-person, family, or other contact. Scrupulous hand-washing, decontamination of equipment – by chemical means if it is heat-sensitive – and use of individual containers for ophthalmic preparations, will terminate an outbreak (Barnard et al. 1973). Other adenoviruses may also be transmitted in this way (Tullo and Higgins 1980). Hospital-acquired bacterial conjunctivitis is common only in neonatal units, where minor conjuctival infection with *S. aureus* is more common than neonatal ophthalmitis due to *Chlamydia trachomatis* or *Neisseria gonorrhoeae* acquired from the birth canal.

THE PERITONEUM

Peritonitis is one of the classical associations of surgery: a breach in the bowel wall is followed by invasion of the peritoneum by a mixture of enteric bacteria, possibly acting synergistically. Advances in the classification and pathogenesis of sepsis, including peritonitis (Bone 1991), have raised the possibility of new therapeutic strategies. Patients who require intensive care have a mortality of 63 percent; amongst the poor prognostic features are advancing age, the presence of septic shock, failure to clear the source of sepsis and an upper gastrointestinal source (McLauchlan et al. 1995).

With the development of peritoneal dialysis for renal failure, and particularly of continuous ambulatory peritoneal dialysis (CAPD) for its chronic management, a very different form of peritonitis has become common. Short-term peritoneal dialysis, in patients unsuitable for hemodialysis, is often complicated by peritoneal infection caused by gram-negative bacilli. CAPD peritonitis has a different spectrum of etiological agents and coagulase-negative staphylococci, particularly *S. epidermidis*, account for about half the cases (Spencer 1988; von Graevenitz and Amsterdam 1992). Factors important in the pathogenesis of such infections include the size of the bacterial inoculum, adaptation of bacteria to the local microenvironment, especially adherence to plastics, and diminished phagocytic activity in peritoneal fluid (von Graevenitz and Amsterdam 1992). Many factors have been invoked to explain the success of *S. epidermidis* as a pathogen in CAPD and there is increasing interest in bacterial phenotypic variation in peritoneal dialysis fluid. Differences in iron-regulating proteins, cell wall and cytoplasmic membrane protein profiles have

been demonstrated when strains are grown in peritoneal dialysis fluid rather than in nutrient broth (Wilcox et al. 1991). Other gram-positive cocci and other skin bacteria, enterobacteria, and the Pseudomonadaceae, account for most other cases. Anaerobic bacteria and fungi are less common. Special cultural methods may be needed to reveal the presence of intracellular organisms or organisms that for other reasons are difficult to grow. The major cause of infection is a lapse in technique by the patient or attendants in changing the containers of dialysis fluid. Patient motivation is therefore important in minimizing infection. A number of specific measures, including good surgical technique at the time of catheter insertion and the use of occlusive dressings (Ludlam et al. 1989), have been advocated to reduce infections, especially those due to *S. aureus*, which are difficult to treat. The infecting organisms may reach the peritoneum from the abdominal skin, with or without overt 'tunnel' infection. Other sources are the bowel – mixed infection with multiple enterobacteria or anaerobes, which suggests perforation (Editorial 1982) – the bloodstream, and the female genital tract. Episodes of infection may be treated with antibiotics without removal of the catheter (Working Party of the British Society for Antimicrobial Chemotherapy 1987), but repeated infection in association with tunnel infection and certain pathogens, such as *S. aureus*, *P. aeruginosa*, and fungi, make success less likely.

Prevention of postoperative wound infection

The measures taken in the operating suite to prevent postoperative wound infection have been classified into the following categories (Medical Research Council Subcommittee of the Committee on Hospital Infection 1968):

- established
- provisionally established
- rational methods
- rituals.

Since then, some time-honored practices have been discarded. Nevertheless, there is still a lack of firm evidence to justify a number of the 'rational' measures that are taken to protect the patient. This chapter gives only an outline that applies to operations generally and not to special situations, such as orthopedic implants. Many measures can be deduced from the risk factors already outlined. Thus, an operation carried out expeditiously with meticulous technique will have a reduced risk of infection.

In elective surgery, patients may be investigated preoperatively at assessment clinics, to avoid a long period in hospital before the operation. Underlying disease and existing infections should, as far as possible, be controlled. Nasal carriage of *S. aureus* is associated with postoperative infection and a review of recent studies found that the relative risk of infection in *S. aureus* carriers was 7.1 (95 percent, CI 4.6–11.0). von Eiff et al. (2001) recently showed that the great majority of cases of *S. aureus* bacteremia appear to be of endogenous origin. Of 14 patients who had nasal colonization with *S. aureus* and subsequent *S. aureus* bacteremia, 12 (86 percent) had nasal isolates indistinguishable from those recovered from blood cultures 1 day to 14 months later. Preoperative monitoring for pathogens, such as *S. aureus* or *S. pyogenes*, is commonly carried out before high-risk operations, such as those on the heart, but its usefulness has not been established (Ridgway et al. 1990). Recent studies have highlighted the potential use of nasal mupirocin prophylaxis to prevent SSIs, notably in patients undergoing cardiothoracic surgery (Kluytmans et al. 1997; Cimochowski et al. 2001), and possibly upper gastrointestinal surgery (Yano et al. 2000). However, a placebo-controlled study of nasal mupirocin prophylaxis in patients undergoing orthopedic prosthetic implant surgery found a reduction in *S. aureus* nasal carriage, but no effect on SSI incidence (Kalmeijer et al. 1999). Wilcox et al. (2003b) observed a marked decrease in the incidence of MRSA SSIs, from 23/1 000 operations to 3.3–4.0/1 000 operations, following the introduction of empirical perioperative prophylaxis based on nasal mupirocin and also including topical skin disinfection with triclosan. A recent placebo-controlled, randomized study of perioperative prophylaxis with nasal mupirocin failed to demonstrate a reduction in the overall rate of *S. aureus* SSIs, but a significant reduction in *S. aureus* nosocomial infections was seen in patients given mupirocin who were *S. aureus* nasal carriers (Perl et al. 2002).

The value of total-body antiseptic treatment, as with chlorhexidine detergent, is also controversial (Lynch et al. 1992). Antiseptic skin preparation in the operating theater, with alcoholic solutions of chlorhexidine or an iodophor, applied with some friction, is very effective (Davies et al. 1978). There is no evidence that longer applications are beneficial, except perhaps when clostridial spores must be removed (Lowbury et al. 1964). The use of specially impermeable material, whether woven or adhesive plastic, or of disinfectant-impregnated material, for the drapes around the operative field, is not supported by firm evidence (Lewis et al. 1984). Hair should, whenever possible, be clipped or removed by depilatory methods rather than by shaving.

A full discussion of the prophylactic use of antibiotics to prevent surgical wound infection is beyond the scope of this chapter (Leaper 1994; Sheridan et al. 1994). The usefulness of very short perioperative courses of aptly chosen antibiotics has been decisively established for operations with a high incidence of endogenous infection. Examples are colonic surgery, upper gastrointestinal surgery in conditions of bacterial overgrowth, some operations on the biliary system, and vaginal hysterectomy. Prophylactic antibiotics are also justified

for operations with a lower incidence of infection when the consequences would be very serious as, for example, for the insertion of orthopedic and other implants, cardiac surgery, and dental procedures in those at risk of endocarditis. The value of such prophylaxis has been established only for joint replacement surgery (Lidwell et al. 1982). Prophylaxis with cephalosporins, which is associated with a very low complication rate, is beneficial for patients undergoing other categories of 'clean' operations. The degree to which this extension of prophylaxis should be encouraged has been debated (Page et al. 1993; Lewis et al. 1995).

The measures customarily taken to establish a safe environment in the operating theater have been reviewed by Hambraeus and Laurell (1980), and the principles of theater suite design by Humphreys (1993). Briefly, ventilation is provided with clean filtered air sufficient in volume to suppress as far as possible the airborne particles produced by human movement, in particular in the region of the operative field. This is far less important in other areas, such as near the floor. The effectiveness of conventional ventilation systems is readily upset by unsatisfactory building design or by undisciplined human activity. Transfer of bacteria from the operating team to the wound is somewhat reduced by the exclusion of staff with clinical infection and by the wearing of clean, frequently changed clothes and an operation gown. However, if the latter is made of conventional fabric, its effectiveness as a barrier to skin microorganisms is small. Masks to filter or deflect upper respiratory particles and caps to reduce contamination from the hair should be worn by the immediate surgical team (Dineen and Drusin 1973). Hand-washing with chlorhexidine or iodophor solutions before donning gloves should be careful and thorough, but not necessarily prolonged (Larson 1984). Gloves are very commonly perforated during operations, and this may be associated with an increased risk of infection for the patient (e.g. Cruse and Foord 1973) and of blood-borne infection for the surgeon (Palmer and Rickett 1992).

Effective sterilization of surgical instruments, with a large margin of safety (Russell et al. 1992), is now universal, but it was not always so (Howie 1988). Heat-sensitive equipment may give rise to difficulties and the need for a rapid turnover may force the use of less stringent decontamination methods, even for instruments that penetrate tissue.

THE URINARY TRACT

Most healthcare-associated infections of the urinary tract are associated with urethral catheterization. Even the single passage of a catheter is associated with a definite, though usually low, infection risk (Kunin 1987). The need for catheterizations should be carefully assessed in each patient and alternatives considered such as self in–out catheterization in females and external catheter in males (Pearman 1998). With an indwelling catheter eventual colonization of the bladder is almost inevitable, but it may be considerably delayed by the system of closed drainage, first introduced by Dukes (1929) and developed by Gillespie and others (Gillespie 1956; Miller et al. 1958). The closed system is not interrupted for the taking of urine specimens, and irrigation after operation can be provided without opening the system (Miller et al. 1958).

In spite of closed drainage, bladder colonization nevertheless occurs. It may reach about 10 percent of patients per day (Kunin and McCormack 1966). The route of infection is not via the lumen of the catheter, but between the catheter and the urethral wall. Early infection is by local commensals, such as *E. coli*, coagulase-negative staphylococci and enterococci. Later, more resistant hospital-associated gram-negative bacilli such as *Klebsiella*, *Proteus*, *Serratia*, *Pseudomonas*, and *Providencia* spp. may invade, particularly under the selective influence of antibiotics. Careful passage of the catheter by skilled staff under conditions of strict asepsis and scrupulous catheter care thereafter are also important (Falkiner 1993; Pearman 1998). Much attention has been given to the use of disinfectants in preventing infection (Stickler and Chawla 1987). Chlorhexidine may usefully be included in the local anesthetic applied to the urethra, or used as an initial 'flush' after the catheter has been passed. Chlorhexidine irrigations reduce the colonization rate (Kirk et al. 1979), but the prolonged application of chlorhexidine may damage the bladder mucosa. Little evidence supports the use of disinfectants in established infection (Davies et al. 1987) or in the long-term protection of indwelling catheters (Stickler and Chawla 1987). Periurethral disinfection, beyond simple toilet, has not been shown to be beneficial (Burke et al. 1983), nor has the inclusion of disinfectants in the catheter-drainage bag (Gillespie et al. 1983). They may, however, prevent the spread of resistant strains of bacteria (Noy et al. 1982), presumably via the hands of those who empty the drainage bags. Such spread is better avoided by an improved nursing regimen. The bacteria that cause urinary tract infection are variably sensitive to the antiseptics that can be used in contact with tissues (Hammond et al. 1987), especially when the bacteria are present in biofilm on the surface of the bladder (Stickler et al. 1987). It has been suggested, but not proved, that extensive use of chlorhexidine may account for the spread of relatively resistant gram-negative bacilli in certain hospital departments (Dance et al. 1987).

The presence of bladder bacteriuria is benign and symptomless in many patients, but its subtle long-term effects have not been studied, and upper tract infection may itself be silent. There is no doubt that urinary infection prolongs hospital stay and worsens the prognosis (Jepsen et al. 1982). The prevalence of hospital-acquired urinary infection was lower in a recent study in the UK and Ireland when compared with 1980 (Emmerson et al.

1996) and this may reflect improved practice and catheter care. A proportion of patients develop pyelonephritis and other complications, such as epididymo-orchitis. Urinary tract infection is one of the most common causes of bacteremia in hospital. It frequently follows urethral procedures (catheter passing, catheter removal, cystoscopy, transurethral prostatectomy) in patients with colonized urine and may lead to septicemia and even death. Thus, perioperative bacteremia was demonstrated by Murphy et al. (1984) in 60 percent of patients with infected urine undergoing urethral operations and, in similar patients in the same hospital, Cafferkey et al. (1982) recorded 6 percent of clinical septicemia arising in these circumstances. Of 31 patients with postoperative septicemia investigated by Cafferkey et al. (1980), eight suffered severe shock and four died.

The risk of septicemia may be avoided by the preoperative or perioperative administration of suitable antibiotics to patients with colonized urine, especially those due to undergo urological procedures, such as prostatectomy and bladder resection (Amin 1992). There may also be a case for the administration of antibiotics to patients with sterile urine who have had indwelling catheters for some time, because damage to the urethra may encourage significant passage of bacteria into the bloodstream. In a study of prophylactic ciprofloxacin in carefully selected patients undergoing vaginal repairs, there was a reduction in symptomatic and asymptomatic bacteriuria compared with controls (van der Wall et al. 1992), but the long-term implications in terms of cost and the emergence of resistance should be carefully considered before this can be recommended for routine use. Antibiotic prophylaxis has no place in other situations and treatment of urinary infection in the catheterized should be limited to dealing with clinical illness (Gillespie 1986).

Silver impregnated antimicrobial urinary catheters have been proposed as a way of reducing associated infection. However, a recent review of the studies in this area concluded that general poor study design means that claims of efficacy cannot be accepted with confidence (Niel-Weise et al. 2002). The one high quality study identified by the reviewers did not demonstrate superior efficacy of silver coated versus standard catheters (Thibon et al. 2000). Alternatives to bladder catheterization that may be feasible are suprapubic catheterization, which has in some studies been accompanied by less bladder infection than urethral catheterization, and intermittent catheterization, including self-catheterization, which may be successful in patients with neurogenic bladder disorders (Pearman 1984). When catheterization appears necessary to achieve dryness in incontinent patients, external, condom drainage may be used, or effective incontinence pads may be substituted with success (Nordqvist et al. 1984), with other measures to encourage regular micturition.

THE RESPIRATORY TRACT

Infections of the respiratory tract represent a significant proportion of all healthcare-associated infections. In the recent prevalence study, respiratory tract infection accounted for approximately 25 percent of hospital infection and was as common as that of the urinary tract (Emmerson et al. 1996). Mortality is between 25 and 35 percent, but depends on the patient population, the diagnostic approach, and whether the mortality rate is crude or takes into account other factors that contribute to a fatal outcome.

A firm diagnosis of pneumonia is not easy to make and it is even more difficult to establish its microbial etiology. Sputum may be contaminated with bacteria from the upper respiratory tract and cultures may give misleading results. The use of bronchoscopic or alternative nonbronchoscopic approaches in the intensive care unit to obtain representative samples from the lower respiratory tract with quantitation of the organisms isolated is increasingly emphasized (Baselski and Wunderink 1994). The results from brush and lavage specimens correlate with histology even in patients on antimicrobial therapy (Chastre et al. 1995). Bronchoscopy may not, however, always be possible and it requires experience. Nonbronchoscopic lavage, with a catheter inserted through an endotracheal or tracheostomy tube, combined with semiquantitation, can be incorporated into routine practice relatively easily (Humphreys et al. 1996).

The etiology of pneumonia varies according to the patient population, diagnostic approaches used, local practices and procedures, and geographical location. Gram-negative bacilli, especially *P. aeruginosa* and *S. aureus*, account for the majority of cases (Dal Nogare 1994), but *S. pneumoniae* may be responsible for up to 20 percent of nosocomial pneumonia (Berk and Verghese 1989). Resistant enterobacteria, e.g. *Klebsiella*, *Serratia*, and *Enterobacter* spp., *P. aeruginosa*, *Acinetobacter* spp., and methicillin-resistant *S. aureus* (MRSA) pose particular difficulties, especially in high dependency areas of hospitals, because of fewer treatment options and the propensity of some of these organisms to spread. For a more general account of the etiology of pneumonia, see Bacterial infections of the lower respiratory tract.

The general conditions that predispose to pneumonia are similar to those for wound infection: obesity, advanced age, and some underlying diseases. The most important factors, however, are respiratory intubation and tracheostomy. Tracheal intubation removes an important barrier to invasion of the lower respiratory tract, and even brief intubation allows oropharyngeal bacteria to pass into the trachea (Nair et al. 1986). High gastric pH, often induced deliberately to prevent stress ulcers in patients in intensive therapy, encourages overgrowth of potential pathogens that may then pass into the respiratory tract of the intubated patient. It has been

suggested that fibronectin is a barrier to colonization by *P. aeruginosa* and that it is breached by the increased protease content of saliva during illness (Woods et al. 1981). Molecular approaches to understanding the pathogenesis of pneumonia reveal a complex interaction between host factors, such as cytokine release, phagocytosis and lymphocyte activation, and virulence determinants of the pathogen, including lipopolysaccharide and bacterial enzymes, such as elastase. For patients in the ICU this is further complicated by other conditions such as the adult respiratory distress syndrome (Meduri and Estes 1995; Harmanci et al. 2002).

Sporadic cases and outbreaks of pneumonia may be associated with contamination of respiratory equipment, such as anesthetic machines, ventilators, humidifiers, nebulizers, resuscitation equipment, and suction catheters (Hovig 1981). Better design of equipment, improved decontamination methods and the use of filters may lessen the importance of these sources. Breathing circuit change intervals of 7 and 30 days have been found to be associated with lower risks of ventilator-associated pneumonia than a 2-day interval, and the difference yielded marked reductions in morbidity and labor and acquisition costs (Fink et al. 1998). In general, there are two main targets within ventilators where filters may be used: firstly, to protect against contamination of the internal parts of the ventilator itself by microorganisms in respiratory secretions (internal filter), and second, to prevent dissemination of microorganisms in respiratory secretions into the external environment, i.e. filter situated on the exhalation limb of the tubing (external filter). To change filters between operations is expensive and there is no conclusive evidence that this will reduce crossinfection. Also, there are no data to prove whether contamination of ventilator circuits is implicated in the etiology of pneumonia. Both pleated hydrophobic and electrostatic filters can be shown to be permeable to bacteria and viruses in vitro. In short, there are no evidence-based guidelines that support the use of filters, and no recommendations about filter type can be made on infection control grounds alone (Das and Fraise 1997; Thomachot et al. 1999). The importance of maintaining respiratory equipment in good order and of cleaning/decontamination has become better recognized after outbreaks with highly resistant bacteria such as *Acinetobacter* spp. (Vandenbrouke-Grauls et al. 1988; Getchell-White et al. 1989; Hanberger et al. 2001). The causative bacteria may also be spread by indirect hand contact, and from there colonize the oropharynx before causing infection. Antibiotic administration encourages colonization by more resistant gram-negative bacilli.

The above account indicates some of the appropriate preventive measures. These include hand-washing, early removal of nasogastric and endotracheal tubes, maintenance of gastric acidity, and elevating the head of the bed to 30° (Dal Nogare 1994). This conventional approach to prevention, with an assessment of which practices have been validated, has been expanded upon elsewhere (Tablan et al. 1994). Nebulized antibiotics for prophylaxis may at first give satisfactory results, but later lead to problems with resistant bacteria (Feeley et al. 1975). Selective decontamination of the digestive tract (SDD), incorporating the use of topical antimicrobial agents to preserve colonization resistance and the protective effect of normal flora (van der Waaij et al. 1990), has been advocated to reduce ICU-acquired infection, including pneumonia (van Saene et al. 1992). The results have, however, been conflicting and have led some to advise against its routine introduction as a preventive measure particularly because of the potential for selection of multiresistant bacteria, such as MRSA (Hamer and Barza 1993; Hurley 1995). In a recent re-evaluation of SDD, de Jonge et al. (2003) carried out a prospective, controlled, randomized, unblinded study on 934 patients admitted to a surgical and medical ICU who were randomly assigned oral and enteral polymyxin E, tobramycin, and amphotericin B combined with an initial 4-day course of intravenous cefotaxime or standard treatment. They found that SDD use was associated with a significant reduction in ICU and hospital mortality and colonization with resistant gram-negative aerobic bacteria. Importantly, the authors note that their findings may not be applicable to units with endemic vancomycin-resistant enterococci or MRSA.

Though legionellosis (see section on Legionnaires' disease) is predominantly community-acquired, nosocomial cases accounted for 15 percent of cases in England and Wales between 1980 and 1992 (Joseph et al. 1994). Hospital-acquired infection should prompt a search for its source and for active preventive measures, including chemical disinfection, control of circulating water temperature, and surveillance (Hoge and Breiman 1991; Joseph et al. 1994). In young children, RSV and at times other viruses, such as enteroviruses, are significant causes of hospital-acquired respiratory infection. Without special precautions, nosocomial acquisition of RSV can be high, and a combination of cohort nursing and the use of gloves and plastic aprons significantly reduces spread (Madge et al. 1992).

Infection associated with indwelling medical devices

The increasing practice of inserting devices, usually made of various plastics, into the body of patients, and the selection pressure of antibiotics, have shifted the spectrum of significant microorganisms commonly encountered in diagnostic laboratories.

Almost every type of indwelling device may become colonized. The predominant bacteria are coagulase-negative staphylococci, particularly *S. epidermidis*. Othercolonizing organisms are *S. aureus* and other skin organisms such as corynebacteria, including

Corynebacterium jeikeium (see Human microbiota; 32, *Staphylococcus*; and 39, Corynebacteria and rare coryneforms), propionibacteria, streptococci, many of low-grade pathogenicity, various gram-negative aerobic bacilli, yeasts, and filamentous fungi. *S. epidermidis* strains associated with such infections appear to produce greater quantities of extracellular slime than do strains from other sources. The slime consolidates bacteria adherent to the polymer surface and interferes with the body's response to infection (Gristina et al. 1993; Jansen and Peters 1993).

INTRAVASCULAR CANNULAE

Plastic cannulae allow infusions to be given via the same vessel for much longer than do steel needles, but they are also associated with bacterial colonization and resulting infection (Maki et al. 1973). At first it was recommended that the site of infusion should be changed frequently, but with better materials, better cannula design, and careful placement, cannulae such as the Hickman and Broviac catheters may now be left in situ for long periods, albeit with a low but significant infection rate (Darbyshire et al. 1985).

The colonization of intravascular cannulae may remain silent or be associated with a simple fever. However, if it is due to more pathogenic organisms, especially *S. aureus*, it may result in septicemia or disseminated infection. Even with *S. epidermidis*, metastatic infection, particularly of other prosthetic material, endocarditis or even immune-complex nephritis, such as that associated with cerebrospinal fluid shunts, may occur. The rate of colonization of intravascular cannulae is very variable, depending on the site of cannulation, the fluid infused, the plastic used in the cannula, the design of the cannula, and the care to achieve asepsis at insertion. Investigations up to 1973 have been reviewed (Maki et al. 1973). The use of lower limb veins is associated with an increased incidence of infection, as is umbilical cannulation in babies. Subclavian catheters are associated with lower infection rates than those placed in the internal jugular vein. Solutions for total parenteral nutrition readily support microbial growth and, alone or in admixture with circulating plasma near the cannula, they encourage colonization and a high risk of catheter-related bloodstream infection (CRBSI). The use of the same line for infusion of blood products and clear fluids, or its use for pressure monitoring and the taking of blood specimens, also increases the colonization rate.

The cuff of the implanted Hickman or Broviac catheter may prevent infection from tracking between catheter and tissues. The importance for cannula colonization of a side port closely related to the cannula is the subject of controversy. Reports of side port colonization are common, but there seems to be no significant difference in the rate of CRBSI between cannulae with and without side ports (Cheesbrough et al. 1984). Careful adherence to instructions for the setting up and care of the infusion reduces the rate of colonization and subsequent infection. The source of colonizing organisms is usually the skin of the patient. Several studies have shown a correlation between microorganisms on the skin and those recovered from the catheter after removal (e.g. Fuchs 1971). For this reason, careful antiseptic preparation of the skin before cannula insertion, preferably with alcoholic chlorhexidene, toilet of the area, and careful choice of dressings to prevent skin maceration is advocated. The application of antibiotic or antiseptic preparations to the entry site once the catheter is in situ is not recommended and may be associated with candidal overgrowth (Norden 1969). In some circumstances, as with Hickman and Broviac catheters with their cuff and protective tunnel, and other central lines, but also at times with simple peripheral cannulae, contamination of the connections of the cannula with the administration set and other reservoirs appears to be of importance (Sitges-Serra et al. 1983; Cheesbrough et al. 1984; Weightman et al. 1988). Care with manipulation of the apparatus may be important in cannula colonization, as it is in contamination of fluid in the rest of the system. Occasionally, cannulae are infected by the hematogenous route (Maki et al. 1973). Preventive measures and their success, depends on the postulated entry route for microorganisms (Weightman et al. 1988; Parras et al. 1994). The route of infection may determine the preponderant site of colonization, whether the microorganisms are on the outside of the cannula or in the lumen, and thus the best means of culturing the cannula tip after its removal. The technique devised by Maki and colleagues (1977) for peripheral cannulae may not be as suitable for central lines. This approach requires line sacrifice and it is known that the majority of central venous catheters removed on suspicion of CRBSI are ultimately shown not to be infected. Catheter colonization may be detected in lines already being used for the taking of blood, by comparing the microbial concentration in a specimen of blood taken through the cannula with one from a distant vein; a simple pour-plate method will suffice (Weightman et al. 1988). An even simpler approach is to compare the time taken for central versus peripheral blood cultures to become positive with the same microorganism. If the time difference is at least 2 h (in favor of the central blood cultures) then this is highly predictive of CRBSI (Blot et al. 1999; Seifert et al. 2003). Other new approaches to the diagnosis of CRBSI which do not rely on catheter removal include the acridine orange leukocyte centrifugation test and the endoluminal brush (Kite et al. 1999). Luminal colonization of intravascular catheters is probably almost universal, particularly as dwell time increases, and thus it is CRBSI which is the clinically important endpoint and not catheter colonization.

Minocycline-rifampin (MR) and chlorhexidene silver sulfadiazine (CSS) containing catheters have both been

shown to reduce the incidence of CRBSI compared with uncoated/impregnated central venous catheters (CVC). A study comparing MR and CSS catheters found significant differences in favor of the former in terms of both prevention of catheter colonization (22.8 versus 7.9 percent, $p < 0.001$) and CRBSI (3.4 versus 0.3 percent, $p < 0.002$) (Darouiche et al. 1999). The enhanced efficacy of the MR catheters is probably due to the fact that these have antimicrobial coatings on both the outer and inner surfaces, whereas only the outer surfaces of CVCs were coated with CSS. Meta-analyses of studies on the efficacy of antimicrobial impregnated CVCs have reached differing conclusions. A recent review of 11 randomized studies identified several methodological flaws, including inconsistent definitions of CRBSI, failure to account for confounding variables, suboptimal statistical and epidemiological methods, and rare use of clinically relevant endpoints (McConnell et al. 2003). This review also failed to demonstrate any significant clinical benefit associated with the use of antimicrobial-impregnated CVCs for the purpose of reducing CRBSI or improving patient outcomes.

INTRAVASCULAR GRAFTS

A similar spectrum of microorganisms is seen in infected cardiac valve prostheses and patches of polymers, and grafts in vessels (Liekweg and Greenfield 1977). This may be influenced by the antibiotic prophylaxis in use, because this may alter the flora of patients and hospital staff (Archer and Armstrong 1983). A multicenter randomized controlled trial of rifampicin-bonded Dacron grafts in aorto-femoral surgery demonstrated a reduction in total early wound and graft infection rates. However, results after 2 years showed a small, nonsignificant reduction in graft infection (1.7 percent in study group, 2.3 percent in control group) (Pratesi et al. 2001).

Endocarditis on prosthetic valves may be caused by microorganisms implanted at the time of operation or soon afterwards (Marples et al. 1978) when many intravascular lines are in situ and the graft has not yet become endothelialized. It may follow sternal-wound infection (Braimbridge and Eykyn 1987) or it may arise later from hematogenous seeding, as happens with diseased natural valves. This latter gives a microbial spectrum close to that seen in infections of natural valves (Heimberger and Duma 1989). Though the incidence of early prosthetic valve endocarditis is now less than 1 percent, the mortality is high. Perioperative infection may manifest after a delay and the various types of endocarditis cannot be separated by an arbitrary time after the operation (Braimbridge and Eykyn 1987; Freeman 1995). An incidence in the first year of 1.4–3.0 percent has been calculated (Karchmer 1991). Reliance should be placed on general measures to prevent perioperative infection and on antibiotic prophylaxis at critical times when bacteremia is likely (Karchmer 1991).

JOINT PROSTHESES

Infection of total joint replacements is a very serious and costly complication and a variety of preventative measures that contribute to minimizing this have recently been well reviewed (An and Friedman 1996; Gosden et al. 1998). As techniques have improved, the incidence has fallen from approximately 12 percent to less than 2 percent for hip replacements, and from approximately 15 percent to less than 4 percent for knee replacements. The effects of ultraclean air and of prophylactic antibiotics on the incidence of infection have been discussed above. In addition to the use of systemic antibiotics, incorporation of antibiotics in the bone cement is now standard practice for revision operations and is used by some in primary operations. Gentamicin may be used, or alternatively a heat-stable antibiotic can be chosen to correspond to known infecting strains (Strachan 1993). The spectrum of infecting bacteria (An and Friedman 1996) is dominated by *S. aureus* and coagulase-negative staphylococci, with smaller numbers of enterobacteria and other gram-negative bacilli. The prognosis of infections with gram-negative organisms is worse after reoperation than infections with gram-positive organisms (Buchholz et al. 1981). Fungal infection is rare. Some recent series have shown increased numbers of streptococci (especially of enterococci) and of anaerobic cocci. Infection of a joint prosthesis almost always requires its removal, with replacement as a one- or two-stage procedure, under local and general antibiotic cover. Occasionally, with a low-grade pathogen sensitive to oral antibiotics infecting a stable joint, medical treatment may succeed, but this form of management should rarely be undertaken as it is beset with complications.

CEREBROSPINAL FLUID SHUNTS

In ventriculoatrial or ventriculoperitoneal shunts, infection may give rise to systemic illness from bacteremia, to ventriculitis or to shunt blockage. *S. epidermidis* is by far the most common infecting agent (Ersahin et al. 1994). As in the case of cannula infections, there may be a long lag between colonization and clinical illness. Most infecting organisms are probably implanted in the tissues at the time of operation (Pople et al. 1992), but other routes may occasionally be followed (Price 1984; Ronan et al. 1995). These infections are managed by a combination of surgical management, including shunt removal and chemotherapy (Bayston 1985; Walters 1992). There is no consensus about the benefits of prophylactic antibiotic use in shunt insertion (Brown 1993), but a meta-analysis suggests a statistically significant advantage (Haines and Walters 1994).

Bacteremia

Hospital-acquired bloodstream infections constitute a serious health problem and are associated with high

morbidity and mortality which results in increased healthcare costs. Each year, as many as 35 million patients are admitted to hospital in the United States. Of these, at least 2.5 million will develop a hospital-acquired infection with almost 250 000 attributable to bloodstream infections (Correa and Pittet 2000). Extensive studies in the USA have reported hospital-acquired bacteremia in 0.2–0.4 percent of hospital admissions. These account for about half the total bacteremias observed. Much higher rates have been reported for tertiary referral centers than for general hospitals (Bryan et al. 1986).

The microorganisms that cause hospital-acquired bacteremia and the circumstances in which they do this are fully discussed in Bloodstream infection and endocarditis. Briefly, the infecting organism may arise from a focus of infection in another system (secondary bacteremia) or no source may be identified clinically or after additional investigations, such as ultrasound (primary bacteremia). The organisms isolated and their resistance to antibiotics to a large extent reflect those prevailing in the hospital. In a study conducted in a UK tertiary referral center, *E. coli* was the most common cause and accounted for 27 percent of cases, followed by other enterobacteria and *S. aureus* (11 percent); polymicrobial bacteremia was responsible for 7 percent of cases (Ispahani et al. 1987). Between 1980 and 1992, the crude bacteremia rate in a US center increased from 6.7 to 18.4 per 1 000 patient discharges and a considerable proportion of this increase was due to gram-positive cocci (Pittet and Wenzel 1995). An increasing proportion of bloodstream infections due to coagulase-negative staphylococci, enterococci, and *Candida* spp. has been documented in recent years. This may reflect the changing hospital patient population and the increasing use of invasive devices. Central venous lines and blood transfusion were independent risk factors for hospital-acquired bacteremia in Australia (Duggan et al. 1993). Coagulase-negative staphylococci are especially important in the pediatric age group and were responsible for 43 percent of bacteremia in Great Ormond Street Hospital, London, UK (Holzel and de Saxe 1992). They were the third most common bloodstream pathogen after group B streptococci and *S. aureus* in a Swedish neonatal unit (Faxelius and Ringertz 1987).

The increasing proportion of bacteremia due to gram-positive bacteria is seen in immunocompromised patients who may require an in situ intravascular device for a long period and for whom repeated courses of broad spectrum antimicrobial agents are often necessary. Viridans streptococcal bacteremia in neutropenic patients is associated with chemotherapy-induced mucositis as shown by the finding that blood and oral isolates were indistinguishable by ribotyping (Richard et al. 1995). Enterococcal bacteremia, especially that due to *Enterococcus faecium*, is closely linked with the presence of cancer, neutropenia, renal failure, steroids, and recent antibiotics (Noskin et al. 1995a). The risk factors for candidemia are similar, but include recent abdominal surgery (Nielsen et al. 1991). On the other hand, the incidence of bacteremia due to *Bacteroides* spp. has declined in many places since the introduction of effective prophylaxis for operations on the large gut (Young 1982).

Clusters of cases may reflect a hospital outbreak of infection. Thus, nine cases of gram-negative bacteremia involving different organisms and occurring after open heart surgery were traced to an aqueous disinfectant used to clean pressure-monitoring equipment that was assembled before surgery and left open and uncovered overnight in the operating theater (Rudnick et al. 1996). Care must be taken to exclude pseudobacteremia, due to the contamination of blood culture media or their additives, contaminated skin disinfectants, specimen containers or blood-gas analyzers or, in the laboratory, from contaminated apparatus or carriers among the staff (Maki 1980).

Mortality rates depend largely on the age and underlying illnesses of the patients, whether there is a removable or remediable focus of infection, and on the microbial cause. Thus, infection with enterobacteria has a worse prognosis than infection with coagulase-negative staphylococci. Polymicrobial bacteremia also has a poor prognosis. Candidemia is associated with a mortality of 76 percent (Nielsen et al. 1991), which reflects the severity of underlying disease in such patients. In the intensive care patient with severe sepsis and shock, bacteremia is associated with a poor outcome, but the category of organisms appears to be less important (Brun-Buisson et al. 1995). Recent efforts to develop and use monoclonal antibodies directed against the gram-negative bacterial cell wall or cytokine mediators, such as tumor necrosis factor (TNF) in these patients, have been disappointing. A multicenter study in 15 centers revealed that blocking TNF activity with high doses of a competitive inhibitor led to a higher mortality compared with placebo (Fisher et al. 1996). Recently, recombinant activated protein C has been made commercially available for use as adjunctive treatment of severe sepsis accompanied by multiple organ failure. Further work on the pathogenesis of severe sepsis and bacteremia will be necessary before useful and safe immunomodulatory agents can routinely be used in management.

For bacteremia resulting from the contamination of intravenous fluids or additives to these, see the section on Infection from contaminated infusion fluids.

Since April 2001, all English hospital trusts have been obliged to report the number of patients with *S. aureus* bacteremia, along with methicillin/oxacillin sensitivity of the isolate. The current 3-monthly report considers the MRSAs amongst these, and dividing the total by the average daily bed occupancy of each hospital trust produces an index of MRSA bacteremia rates per 1 000 bed-days. The 186 hospital trusts are then ranked

according to their bacteremia rates. At the bottom are a few centers that can congratulate themselves on rates of zero, whilst at the other extreme, high ranking trusts will have to explain MRSA bacteremia rates of up to 0.69 per 1 000 bed-days (Barrett and Spencer 2002).

The wide release of these figures adds to the increasing profile of hospital infections in the English public's awareness, which in turn should be viewed in the context of longstanding media interest in health-service shortcomings. Although the exact relevance of MRSA is debated, collecting MRSA bacteremia data has a certain logic. As a mainly hospital-acquired organism, it can be inferred that MRSA in blood culture suggests that a serious hospital-acquired infection has occurred. However, this does not allow for the unknown but increasing reservoir of common MRSA entering hospitals. In one locality, 17 percent of nursing home residents carried MRSA (Fraise et al. 1997). The higher the rate, by inference, the worse must be the individual hospital trust's problems with hospital-acquired infection – or at least its prevalence of MRSA. Moreover, extracting the numbers from laboratory computers and workload databases is vastly cheaper and quicker than surveillance of infections by clinical documentation. Appropriate surveillance techniques constitute the cornerstone of infection control and make possible the implementation of specific preventive approaches. Furthermore, accurate surveillance may identify risk factors for infection and other adverse hospital-acquired events (Correa and Pittet 2000). Surveillance of hospital-acquired bacteremia may appear straightforward because of the simple definition of the infection. Review of the microbiology laboratory records certainly allows identification of most of the cases. However, clinical sepsis is a recognized entity that may not be associated with positive blood cultures. In 2003, mandatory reporting of glycopeptide-resistant enterococcal bacteremia also began.

HOSPITAL INFECTION AT THE EXTREMES OF LIFE

Geriatric and long-stay facilities

Hospital infection and infection control in aged patients have been somewhat neglected, but their importance is undeniable. Patients older than 65 years account for a disproportionate number of healthcare-associated infections (Smith 1988). The relative frequency of infection at different sites depends, for example, on whether simple colonization of the bladder or of an ulcer is included, but the three most frequently infected systems are the respiratory tract, the urinary tract, and the skin. The last is more common in long-stay units (Darnowski et al. 1991; Jackson et al. 1992) than in acute geriatric units (Hussain et al. 1996).

Particular difficulties may be the declining defenses and multiple underlying chronic diseases in the patients and, in some long-stay hospitals, a lack of facilities, including isolation facilities, low staffing levels, and a comparative lack of access to medical assessment. Patients may be ambulant and have poor hygienic practices, and there may be close contact among patients. This may result in the spread of infections, such as adenovirus conjunctivitis, ringworm, scabies, etc., not seen in acute units. Chronic infections, such as tuberculosis, may spread insidiously. Carriage of MRSA may cause more severe problems when patients are transferred to surgical units or other services with vulnerable patients than in the geriatric unit itself (Combined Working Party of the British Society for Antimicrobial Chemotherapy and the Hospital Infection Society 1995). Infections in nursing homes have been reviewed by Nicolle et al. (1996).

Long-term indwelling urethral catheters are common in the elderly. Most surveys have shown a high prevalence of bacteriuria due to a number of different species. The most common are of *Proteus* or *Providencia* spp. rather than *E. coli* (Standfast et al. 1984; Lee et al. 1992). The clinical significance of most of this bacteriuria may be doubted (Jewes et al. 1988).

Nosocomial pneumonia in the elderly resembles that in younger age groups, in terms of etiology and in risk factors such as tracheal intubation, but it is associated with malnutrition and neuromuscular disease and has a particularly poor prognosis (Craven et al. 1992; Hanson et al. 1992; Woodhead 1994). Infection by respiratory viruses, including influenza A, is common and may cause serious illness and death.

The grave consequences of salmonella infection in aged patients have been reported frequently (e.g. Committee of Inquiry 1986). Clusters of cases of diarrheal disease are common. When an etiological agent is identified it is frequently a Norwalk-like virus (Stevenson et al. 1994; Augustin et al. 1995), but rotavirus outbreaks have also been reported (Holzel and Cubitt 1982).

Over 80 percent of *C. difficile* diarrhea cases in the UK occur in hospitalized patients aged over 65 years. Notably, the frail elderly are more prone to severe *C. difficile* infection (Kyne et al. 1999). Antibiotic use is the prime risk factor, but others linked to severe *C. difficile* diarrhea include functional disability, cognitive impairment, recent endoscopy, and possibly enteral tube feeding. *C. difficile* infection appears to be a marker, but not a cause per se, of increased risk of dying (Wilcox et al. 1996; Kyne et al. 1999, 2002). Further details about *C. difficile* infection can be found below and in *Clostridium perfringens*, *Clostridium difficile*, and other *Clostridium* species.

Neonatal units

Intrauterine and perinatal infections of maternal origin, such as rubella, listeriosis, group B streptococci infection, candidiasis, and infection by HIV will not be

considered here. However, many of these agents may, occasionally, be spread among babies via staff or equipment.

Unlike well-baby nurseries, the prevalence of infection may exceed 20 percent in neonatal intensive therapy units, and on this there may be superimposed outbreaks of infection by particularly virulent and usually antibiotic-resistant strains. The babies in these units, particularly when premature, have undeveloped defenses and lack a normal flora. Ill babies require much handling by staff, and it is therefore difficult to prevent the spread of infection by contact from one to another.

Infection with *S. aureus* was the main concern in the 1950s. Babies in nurseries for the newborn were regularly colonized and some developed septic skin lesions of varying severity that sometimes progressed to fatal generalized infections. The causative staphylococci showed considerable differences in virulence. The problem was ameliorated by standard infection control measures, early discharge of healthy babies from hospital, and prophylactic use of topical hexachlorophane (Alder et al. 1980). A large neonatal outbreak of *S. aureus* identified by routine phage typing required multiple, staged, infection control measures including strict emphasis on hand hygiene, application of topical triclosan solution and hexachlorophane powder, aseptic handling of a skin protectant material, and use of topical mupirocin for staff nasal carriers of the endemic strain and for babies colonized or infected with *S. aureus* (Wilcox et al. 2000b). Withdrawal of hexachlorophane after overdosing had been shown to give rise to neurological damage and was followed by a recrudescence of staphylococcal infections (De Souza et al. 1975; Allen et al. 1994). Control of *S. aureus* in a neonatal unit was maintained when topical umbilical hexachlorophane powder was substituted by 1 percent chlorhexidine powder (Wilcox et al. 2003a). The neonatal unit has often been a focus of infection by MRSA (Reboli et al. 1989; Tam and Yeung 1988). In neonatal intensive therapy units there may occasionally be outbreaks of infection by enterobacteria such as *Klebsiella* spp., *Serratia* spp., and *P. aeruginosa*, sometimes resistant to many antimicrobial agents and with the ability to spread rapidly and cause serious illness (Davies and Bullock 1981; Lewis et al. 1983; Coovadia et al. 1992). Colonization by such bacteria without infection is very common. Routine monitoring of carriage sites contributes little to preventing illness (Jolley 1993), but may help in formulating a rational policy for antibiotic prescribing. Surveillance is better directed towards identifying strains with the potential to spread widely and cause serious illness (Goldmann 1988).

In recent years, *S. epidermidis* or other coagulase-negative staphylococci have been the most frequent cause of infection in many neonatal units (Thompson et al. 1992; Nataro and Corcoran 1994). Such infections are generally more benign than those due to gram-negative aerobic bacilli. The reason for their current prevalence is unknown, but may partly reside in their resistance to commonly used antibiotics and the increased use of intravascular cannulae and respiratory apparatus. Some strains spread within a unit, but there is no evidence of the emergence of particularly virulent or transmissible strains of coagulase-negative staphylococci. Indeed, several different strains may simultaneously infect a single patient (Simpson et al. 1986; Kacica et al. 1994).

Necrotizing enterocolitis has increased in incidence in recent years and has features, such as clustering of cases, that suggest an infective etiology. At times tightening of infection control procedures appeared to abort an outbreak (Willoughby and Pickering 1994). However, attempts to demonstrate a specific microbial cause have been unsuccessful (de Louvois 1986; Gupta et al. 1994).

Outbreaks of virus infection in neonatal units can be serious and difficult to control. Enteroviruses such as echovirus 11 (Nagington et al. 1978), adenovirus 7 (Finn et al. 1988), or adenovirus 8 (Piedra et al. 1992), rotaviruses (Holzel and Cubitt 1982), and RSV (Hall et al. 1979) may be responsible. *Candida* spp. may on occasion cause crossinfection in neonatal units (Finkelstein et al. 1993; Reagan et al. 1995).

THE ROLE OF INDIVIDUAL PATHOGENS

Staphylococcus aureus

This organism has probably always been an important cause of hospital-acquired infection, but it was first seriously investigated in the early years of the antibiotic era (see Williams et al. 1960). Certain strains that could be identified by phage typing (*Staphylococcus*) and were resistant to penicillin, and often also to other antibiotics, became prevalent in hospitals. Some of these multiresistant strains were exceptionally virulent, able to cause severe infections in otherwise healthy persons, and colonized widely. These so-called 'epidemic strains' caused many outbreaks of skin sepsis, most notably in the postnatal period, and were the main cause of postoperative wound infection in the 1950s (Shanson 1981).

During the 1960s, hospital-acquired infection by multiresistant strains became progressively less common (Ayliffe et al. 1979). MRSA strains (*Staphylococcus*) were recognized at this time, but they seldom spread widely. In the late 1970s, however, strains that were methicillin-resistant, and often also resistant to aminoglycosides, became prevalent in many parts of the world and have subsequently spread widely in hospitals. Patients particularly affected are those in hospital for prolonged periods, elderly or debilitated patients, those with wounds or burns, and those who have had recent treatment with antibiotics (Brumfitt and

Hamilton-Miller 1989). Clinical and laboratory evidence suggests that MRSA are not less virulent than sensitive isolates (French et al. 1990) and in severely ill patients under intensive care, mortality from pneumonia may be high (Rello et al. 1994). The financial impact of MRSA is increasingly recognized (Casewell 1995); the additional measures necessary to control an outbreak with a new epidemic strain that involved over 400 patients in England amounted to £400 000 (Cox et al. 1995).

Control of MRSA can be difficult and ward closures can result in the severe disruption of clinical services (Barrett et al. 1993). Nonetheless, active intervention combined with effective surveillance is successful (Hartstein et al. 1995). In the face of endemic infection, control measures are usually based upon a risk assessment of the likelihood of spread and invasive infection, and include selective screening of patients (less so, staff), isolation or cohort nursing, and eradication of carriage by the judicious use of topical antibiotics (Ayliffe 1996; Combined Working Party of the British Society for Antimicrobial Chemotherapy, the Hospital Infection Society and the Infection Control Nurses Association 1998). Recognition of epidemic strains may be assisted by noting the origin of the patient, the clinical illness, the type of infected lesion, the antibiotic-sensitivity pattern, and phage type. Collecting this information and the use of a simple computerized database can provide useful information on local epidemiology (Rossney et al. 1994). The complexity of strains isolated and the presence of phage nontypable strains means that a combination of phenotypic and genotypic typing methods (see later under Epidemiological typing) is now often required to determine source and spread (Tenover et al. 1994). The emergence of MRSA strains with reduced vancomycin susceptibility is of some concern (Hiramatsu et al. 1997). There have been recent reports of outbreaks of community-acquired MRSA infection, particularly in the US, which are caused by strains with a novel methicillin resistance gene and often also a hitherto rare exotoxin, Panton–Valentine leucocidin, that is associated with primary skin infection and pneumonia (Dufour et al. 2002; Mongkolrattanothai et al. 2003; Anonymous 2003). This development raises the specter of the transmission and acquisition of MRSA clones outside the traditional secondary healthcare setting. Basic infection control practice, including the rational use of antimicrobial agents, becomes even more important as we face the possible dissemination of strains for which there are few effective therapeutic agents.

Colonized or infected patients should be treated in isolation, preferably in a single room or designated isolation facility, with precautions against both contact and aerial spread. Contaminated environmental surfaces may be a source for continuation of an outbreak. When large numbers of patients are involved, cohort nursing in separate areas of the hospital may be necessary, but control may be impossible without a dedicated isolation unit (Pearman et al. 1985). Mupirocin seems particularly effective in eliminating carriage (Casewell and Hill 1986), but resistance to this agent can emerge following prolonged or repeated use in MRSA patients and patients with chronic skin disease (Cookson 1990). MRSA carriage may be unresponsive to a variety of antiseptics and increasing numbers of carriers are found in nonacute units and in the community.

Enterococcus spp.

Recent interest in *Enterococcus* spp. as hospital pathogens has focused on unusually antibiotic-resistant strains of *Enterococcus faecium* and *Enterococcus faecalis*. Resistance may be multiple and include high-level resistance to penicillins and to aminoglycosides, such as gentamicin, which are important in providing synergistic bactericidal combinations with penicillins. They may also be resistant to glycopeptides such as vancomycin, which had been regarded as universally active against gram-positive bacteria that may infect humans, apart from intrinsically resistant genera of minor importance such as *Pediococcus*, *Leuconostoc*, and *Lactobacillus* (Woodford et al. 1995; Chavers et al. 2003).

Resistance to vancomycin in enterococci was first reported in a cluster of hospital-acquired infections in the UK (George et al. 1989) and such strains are increasingly found in oncology, renal, transplant, and intensive care units (Hospital Infection Control Practices Advisory Committee 1995). The epidemiology of resistant enterococci is not entirely clear. Treatment, particularly with cephalosporins and glycopeptides, may encourage colonization with enteroccci, which may then spread from patient to patient by indirect contact, via staff and environment, and thus cause persistent problems.

For epidemiological purposes, enterococci may be typed by ribotyping, but pulsed field gel electrophoresis is more discriminating. The strains are heterogeneous, but the evidence suggests that particular epidemiological types spread between hospitals (Chadwick et al. 1996; Morrison et al. 1996). Guidelines for the prevention of spread have been issued in the USA (Hospital Infection Control Practices Advisory Committee 1995) and discussed in the UK (Chadwick et al. 1996). These guidelines are similar to those for the control of MRSA (see above).

Clostridium difficile

C. difficile has emerged during the last decade as a significant hospital-acquired pathogen. It was recognized in the late 1970s as the main cause of antibiotic-associated diarrhea, which may be associated with pseudomembraneous colitis (PMC) (*Clostridium perfringens*, *Clostridium difficile*, and other *Clostridium* species). The number of laboratory reports of *C. difficile* infection sent

to the UK Communicable Disease Surveillance Centre increased ten-fold between 1982 and 1991 (Joint DH/PHLS Working Group 1994). Laboratory reports for *C. difficile* positive samples for England and Wales currently (2002) stand at approximately 29 000 per year (provisional data). This is certainly an under-reporting of the true burden of this disease. *C. difficile* may be part of the normal bowel flora, especially in the elderly, and may also be recovered from the hospital environment. Antibiotics, especially broad spectrum agents, disrupt the normal bowel flora and render patients susceptible to colonization. *C. difficile* rarely, if ever, affects healthcare personnel and spread from patient to staff is unusual.

The increasing numbers of elderly and debilitated patients admitted to hospitals, the misuse of antimicrobial agents and changes in healthcare, including greater diagnostic and therapeutic interventions, have all probably contributed to the increased colonization with *C. difficile*. Whilst most cases are sporadic, clusters or outbreaks also occur. In the UK, a large outbreak involving 175 patients occurred in three hospitals in Manchester in 1992. Most of the patients were over 60 years old and infection was believed to have contributed to 17 deaths (Cartmill et al. 1994). In smaller outbreaks or clusters, epidemiological evidence usually suggests a traceable chain of person-to-person spread between wards or hospitals (Nolan et al. 1987). Apart from significant morbidity and mortality in an already vulnerable population, management and control of this condition have significant financial implications. In a case-control study it was calculated that 94 percent of the additional costs associated with *C. difficile* infection were due to increased duration of hospital stay and the total cost was in excess of £4 000 per case (Wilcox et al. 1996).

Even before the advent of newer typing techniques, clinical and epidemiological evidence suggested that patient-to-patient spread occurred by the fecal–oral route and that precautions were necessary to prevent spread. More than 20 percent of patients may carry *C. difficile* at some stage during hospitalization, especially if they share a room with a positive patient, and environmental and patient isolates are often indistinguishable (McFarland et al. 1989; Samore et al. 1996). Control measures should be aimed at minimizing the risk of antibiotic-associated diarrhea by good antimicrobial prescribing, scrupulous hand-washing, the isolation or cohorting of affected patients, treatment of persistently symptomatic patients, careful disposal of contaminated laundry and, finally, environmental disinfection/decontamination (Joint DH/PHLS Working Group 1994; Gerding et al. 1995; Wilcox 1998). The role of asymptomatic carriers in spread, especially amongst the elderly, remains unclear. Some *C. difficile* strains are more virulent than others. For example, ribotype 1 is epidemic in the UK, being responsible for about 60 percent of reported cases, and posseses several phenotypes that distinguish it from other strains; for example, ribotype 1 sporulates more than comparators, a phenomenon that is enhanced when exposed to detergents (Wilcox and Fawley 2000), and is more resistant to fluorquinolones (Wilcox et al. 2000a). It is known that environmental contamination with *C. difficile* is widespread despite routine detergent-based cleaning (Fawley and Wilcox 2001; Verity et al. 2001). There is some evidence that environmental cleaning with hypochlorite may be more effective than detergent as a control measure for *C. difficile* diarrhea (Wilcox and Fawley 2000; Wilcox et al. 2003b).

Enterobacteriaceae

E. coli is one of the most frequently encountered bacteria in hospital-acquired infection (Jarvis and Martone 1992). It causes urinary tract infection (Bacterial infections of the urinary tract), intraabdominal and gut-related wound infection and bacteraemia (Bloodstream infection and endocarditis and 52, *Escherichia*), but infection is almost always endogenous and sporadic; even resistant strains seldom appear to spread between hospital patients (Hart 1982). However, cross-infection by strains with the potential to cause enteric infection, including verocytotoxin-producing *E. coli* strains, is common in hospitals and other healthcare facilities (Carter et al. 1987; Kohli et al. 1994).

Other Enterobacteriaceae are more important in the spread of nonenteric infection in hospitals. This is due to antibiotic resistance, transmissibility, and virulence, which interact in hospital units that accumulate patients with similar medical problems who undergo similar procedures and receive similar antibiotics. For example, *Klebsiella* spp. have come into prominence in outbreaks caused by multiresistant strains that produce extended spectrum β-lactamases (Johnson et al. 1992; Meyer et al. 1993; Quinn 1994). Ease of transmission from patient to patient, resulting in large-scale epidemics and inter-ward spread rather than small clusters of infections or common-source outbreaks, may be related to better survival on hands (Casewell and Desai 1983) or on inanimate surfaces (Hart et al. 1981), but other factors must be involved (Fryklund et al. 1995). The characteristics of hospital infection by members of the various enterobacterial genera are outlined in Table 1. Infection by *Salmonella* spp. has been mentioned under infection transmitted by food (Bacteriology of foods excluding dairy products and 54, *Salmonella*).

Pseudomonas aeruginosa

P. aeruginosa has been recognized as a pathogen of hospital patients only in the modern era of intensive treatment and antibiotic administration. Its ability to grow in moist conditions with simple nutrients and its comparative resistance to antibiotics and disinfectants have allowed it to become established, often in very large numbers, in fluids and wet places in the hospital

Table 1 *Enterobacteriaceae of importance in hospital infection*

Genus[a]	Source and mode of infection	Circumstances of infection	Antibiotic characteristics of hospital strains	References
Escherichia (*E. coli*)	Endogenous; crossinfection uncommon (except enteric infection)	Common (especially urinary, bloodstream)	Ampicillin R common	Olesen et al., 1995
Citrobacter (*C. freundii*, *C. diversus*)	Infrequent, endogenous infection	Bloodstream, etc.	Often multi-R including cephalosporins	Thurm and Gericke, 1994
Klebsiella (*K. pneumoniae*, *K. oxytoca*)	Endogenous, but crossinfection common, with fecal carriage; transmission via hands	Bloodstream, urinary (especially catheterized), respiratory; ICUs especially neonatal, urological units	Ampicillin R; frequently aminoglycoside R; increasingly R to newer cephalosporins	Johnson et al. 1992; Meyer et al. 1993; Quinn 1994
Serratia (nonpigmented *S. marcescens*)	Crossinfection common, also environmental sources implicated; skin, throat carriage, but fecal carriage less common; hand spread	Urinary, respiratory; ICUs, especially neonatal	R to ampicillin, early cephalosporins; frequently R to aminoglycosides and newer cephalosporins; emergent R during treatment; characteristic polymyxin R	Lewis et al. 1983; Coria-Jimenez and Ortiz-Torres 1994; Luzzaro et al. 1995
Enterobacter (*E. cloacae*, *E. aerogenes*)	Endogenous and hospital infection from common source, e.g. medicaments, food, apparatus; hand spread less common; throat and fecal carriage	Respiratory, urinary, bloodstream; ICUs especially neonatal, burns units	Ampicillin R; frequently R to cephalosporins; emergent R during treatment	Gaston 1988; Weischer and Kolmos 1992
Proteus (*P. mirabilis*, *P. vulgaris*, also *Morganella*)	Endogenous and small clusters; fecal carriage	Urinary, bloodstream; ICUs, urological units	Variable (see *Proteus*, *Morganella*, and *Providencia*)	Williams et al. 1983; Watanakunakorn and Perni 1994
Providencia (*P. stuartii*)	Endogenous; slow transmission among patients; fecal carriage	Urinary, occasionally other sites; geriatric, paraplegia units; mixed infection with *Proteus* spp. common	Aminoglycoside R common	Hawkey et al. 1984; Woods and Watanakunakorn 1996

ICUs, intensive care units; R, resistance or resistant.

a) Only more important species are listed. For *Salmonella*, see Chapter 54.

and to colonize the mucous membranes and skin of patients. Respiratory infection in intensive therapy units, infection of burns, in neonates, in abdominal surgery, and after trauma, are among the most characteristic presentations, but cases may be encountered in any acute hospital unit.

Strains of *P. aeruginosa* can be distinguished by serotyping, pyocine typing, phage typing (*Pseudomonas*) and by genotypic methods. Strains may differ markedly in virulence and some epidemics are caused by particularly virulent strains or by exposure of a sensitive body site, such as the eye, to heavily contaminated fluids or apparatus. Mostly, however, infections are endemic or sporadic, and colonization is more common than clinical disease. Indeed, in some hospital units clinical infection may be rare, though colonization may be almost universal. It may, therefore, be difficult to interpret the significance of the isolation of *P. aeruginosa* from patients' specimens (Davies and Bullock 1981).

Normal subjects may carry *P. aeruginosa* in their bowel. The apparent prevalence depends on the sensitivity of isolation methods (Shooter et al. 1966) and antibiotic treatment encourages such carriage. The importance of strains at inanimate sites in the hospital varies, but their spread to patients has been reported (e.g. Doring et al. 1993). Strains found at such sites are, however, often different from those found in the patients (Kropec et al. 1993). Clearly, there is much greater likelihood of infection when the patient comes into close contact with the infected source or object, such as contaminated medicaments, inhalants, or splashing from sinks. It is, therefore, essential that medicaments and aqueous disinfectants intended for application to patients are supplied sterile and preferably in single-use portions. Patient-to-patient spread may occur when there is a breakdown in infection control measures, such as failure to disinfect urinals and bedpans and failure of hand hygiene (Lowbury et al. 1970). In these situations rectal and other colonization usually precedes infection.

P. aeruginosa is the most common persistent pathogen in chest infection in cystic fibrosis, but the degree to which crosscolonization occurs in hospital units appears to differ widely.

Mycobacterium spp.

In the past, tuberculosis was a serious occupational risk for healthcare staff. This is no longer the case in most clinical situations where tuberculin testing and immunization, supplemented by selective chest X-ray, are available for staff in contact with patients and those handling pathological material (Joint Tuberculosis Committee of the British Thoracic Society 1994). Nosocomial acquisition of tuberculosis by patients in the developed world is also uncommon. Risk factors for transmission to patients and staff include delayed diagnosis, drug-resistant strains and lapses in administrative, engineering, and infection control practices (Menzies et al. 1995). Multidrug-resistant tuberculosis in HIV patients is of increasing concern as presenting a risk to staff and other patients. Previous admission to hospital, failure to isolate positive patients in a single room, and the absence of positive pressure ventilation are associated with spread (Pearson et al. 1992).

The risk of infection depends on the infectivity of the primary source, the duration and proximity of the exposure, and the susceptibility of the recipient (George et al. 1986). Infectivity depends on the amount of cough and the concentration of bacteria in the sputum. Thus, 'three-smear-negative' culture-positive patients with pulmonary tuberculosis and patients with nonpulmonary tuberculosis are usually regarded as noninfective. Sputum infectivity declines rapidly during chemotherapy, including that with rifampicin, with a 99 percent decline in viability after 2 weeks, but scanty bacteria may survive for much longer (Jindani et al. 1980). Isolation for 2 weeks in a well-ventilated side ward, without recirculation of the air to other parts of the hospital, is recommended while patients are infectious (Joint Tuberculosis Committee of the British Thoracic Society 1994). Susceptible individuals are the young and those whose immunity is depressed by disease or treatment. Care should be exercised in the handling of fomites from sputum-positive patients and in protecting highly susceptible patients from exposure (George 1988). This may entail prolonged isolation of smear-positive patients and the segregation of smear-negative or nonpulmonary cases of tuberculosis. Contact tracing should be undertaken after incidents in which staff or patients were exposed to infection (Joint Tuberculosis Committee of the British Thoracic Society 1994). Control measures can halt the transmission of multidrug-resistant strains (Wenger et al. 1995). The use by healthcare staff of HEPA respirators is expensive, inconvenient, and is not believed to be cost-effective (Adal et al. 1994).

Hospital infection, including keratitis and systemic disease, caused by opportunist mycobacteria, such as *Mycobacterium chelonei*, *Mycobacterium gordonae*, and *Mycobacterium fortuitum*, has been observed (Watt 1995). Contributory factors are the ability of these mycobacteria to survive and multiply in moist environments, inadequate decontamination procedures, and poor hygienic precautions in renal dialysis, bronchoscopy, hydrotherapy, and cardiac surgery units (George 1988). Contamination of specimens by the use of tap water to rinse disinfected bronchoscopes has led to 'pseudo-outbreaks' (Nye et al. 1990). The extent to which crossinfection is responsible for the *Mycobacterium avium* complex infections seen in patients with AIDS (*Mycobacterium tuberculosis* complex, *Mycobacterium leprae*, and other slow growing mycobacteria) is unknown. The *M. avium* complex may

be recovered from standing water and food sources (Horsburgh 1991) and clusters of cases may therefore reflect acquisition from a common source rather than person-to-person spread.

Other bacteria

The main features of hospital infection by other bacterial species are given in Table 2.

Viruses

The prevalence of nosocomial viral infection is probably underestimated. Most surveys of hospital-acquired infection concentrate on bacteria and the subclinical nature of many viral illnesses together with limited diagnostic facilities partly explains why viruses do not figure prominently. Viral infections are, however, important in neonatal and pediatric patients and in immunosuppressed patients. In pediatrics, rotavirus may be the most common individual pathogen encountered.

Community-acquired infection by respiratory syncytial virus is almost universal in children in the early years of life. In hospital this is a particular danger to premature neonates and children with cardiorespiratory abnormalities. Staff and adult patients may be reinfected, with minor respiratory symptoms, but severe disease may occur in the immunodeficient adult. The virus spreads by respiratory secretions entering the eye or nose, with or without an intervening period on surfaces or fomites. The risks of infection may be reduced by a combination of cohort nursing and the wearing of gowns and gloves (Snydman et al. 1988; Madge et al. 1992). Such a proactive approach is made possible by the availability of rapid antigen detection facilities (Editorial 1992). Similar principles apply to control of the childhood exanthemata, when infected patients are admitted to hospital (Breuer and Jeffries 1990). Staff working with pregnant women should be immune to rubella. Apart from classical influenza, influenza virus A can cause a variety of syndromes in hospital patients, including a particularly dangerous form of pneumonia in the elderly. Selective immunization of patients can be helpful and a case can be made for the routine immunization of some health workers (Heimberger et al. 1995).

Viral gastroenteritis is common in neonatal and pediatric units, in general wards, and in long-stay accommodation for the elderly (Holzel and Cubitt 1982). Rotavirus is the most frequent causative agent in children. In the elderly, outbreaks of diarrhea caused by SRSV, such as noroviruses, and other agents, can affect large numbers of patients. Spread occurs via the fecal–oral and probably also via the air-borne routes. Prevention of spread may be achieved by early diagnosis, for example by electron microscopy, and strict precautions that include wearing of aprons and gloves, strict hand-washing routines, availability of separate toilet facilities, and restriction on the movement of symptomatic patients and staff caring for them, as well as good communications between hospitals to minimize inadvertent spread (Caul 1994; Rao 1995; Chadwick et al. 2000).

Enterovirus infections, though usually subclinical, are also common in hospitals (Dowsett 1988). Besides hepatitis A, coxsackie A and B and echoviruses may cause generalized febrile infections and meningitis, particularly in the newborn, generalized illness with bowel symptoms in immunodeficient persons, and minor infections in staff. Spread may occur by the oral and respiratory routes and by hands, fomites, and such shared facilities as hydrotherapy pools. The same groups of patients are particularly susceptible to the herpes group of viruses. Cytomegalovirus, as well as being transmitted in utero and at birth from mother to baby, may be conveyed in donations of blood or tissue, and infections in the immunosuppressed often result from reactivation. Varicella-zoster may be conveyed by the vesicular exudate or respiratory secretions of patients with chicken pox and, less frequently, zoster. Both diseases necessitate barrier precautions and patients must be segregated from susceptible persons, who may, when appropriate, be protected with immune globulin (Burns et al. 1998). This will also protect healthcare staff, of whom approximately 15 percent may not be immune. A register of staff immunity may be useful, especially in clinical areas where varicella infection may be more common, such as pediatric wards (Breuer and Jeffries 1990). In the USA, vaccination of susceptible healthcare staff likely to be exposed to patients at high risk of complications of chicken pox is recommended (Bolyard et al. 1998). Herpetic whitlows occasionally develop in staff not protected from exposure to the respiratory secretions of patients.

Viral hemorrhagic fevers such as Lassa, Marburg, and Ebola, have been responsible for infections of hospital staff and patients in tropical countries where equipment and staffing are inadequate and medical practice poor (Fisher-Hoch et al. 1995). In the UK, patients are categorized as minimum, moderate, or high risk. Minimum and moderate risk patients may be cared for in an isolation unit, but those in the high risk group should be tranferred to a high security infectious disease unit (Advisory Committee on Dangerous Pathogens 1996). This may not always be feasible and is in contrast to US recommendations which emphasize isolation in a single room with negative pressure ventilation and the implementation of universal precautions, as spread by the air-borne route is considered relatively rare (MMWR 1995).

For other blood-borne viruses (see section Hepatitis B and C and HIV infection in hospitals).

The control and prevention of viral infection amongst hospital staff is best managed by occupational health departments, by staff screening, immunization, and

Table 2 *Other bacteria[a] associated with hospital infection*

Bacteria	Source and mode of spread	Circumstances of infection	Antibiotic characteristics of hospital strains	References
Gram-positive bacteria				
Coagulase-negative staphylococci	Endogenous; 'hospital' strains by contact, air	Implants; intravascular cannulae; sternal wounds; neonates	Variable; often multi-R especially to isoxazolylpenicillins, aminoglycosides; usually S to vancomycin, rifampicin	Stillman et al. 1987; Patrick et al. 1992
Streptococcus				
S. pyogenes (streptococcus Lancefield group A)	Endogenous; uncommon hospital spread from cases and throat, nose, skin, rectal carriers; contact, air	Wounds, burns, skin lesions; parturient women	Invariably S to benzylpenicillin; variable to erythromycin, tetracycline	Garrod 1979; Easmon 1984
S. agalactiae (streptococcus Lancefield group B)	Endogenous (feces, vagina); occasionally contact in neonatal units	Usually congenital in neonates; postpartum infection; skin and soft tissue lesions	Consistently benzylpenpenicillin S	Easmon 1984; Zangwill et al. 1992
S. pneumoniae	Endogenous; occasionally air spread of more virulent or antibiotic-resistant strains	Pneumonia, etc., in respiratory or general impairment; children	Hospital clusters showing penicillin R or intermediate R and multi-R	Millar et al. 1994
Other streptococci: viridans or indifferent; *S. anginosus* (syn. *milleri*); β-hemolytic streptococci groups C and G	Endogenous; rarely contact spread	Abdominal surgery; implants; neutropenic patients	May be relatively R to β-lactams	Editorial 1984a, 1985
Corynebacteria (especially *C. jeikeium*)	Endogenous; skin colonization may precede infection	Implants; cannulae; immune impairment; antibiotic treatment	Multiple R; vancomycin S	McGowan 1988
Clostridium				
C. perfringens, etc.	Usually endogenous (feces); indirect contact spread of enteritic strains	Abdominal surgery; amputations; diabetics: elderly (enteritic)	Benzylpenicillin S	Lowbury and Lilly, 1958; Borriello and Barclay, 1986
C. tetani	In the past, environmental and operative materials; now possibly endogenous	Very rare postoperative infection	Benzylpenicillin S	Parker and Mandal 1984
Bacillus spp.	Environmental; may resist sterilization processes	Opportunistic; soft tissue and occasional systemic infection	Often R to β-lactams	Weber and Rutala 1988
Rhodococcus equi	Unknown, possibly by air from soil, etc.	Pneumonia, etc., in immunocompromised, e.g. HIV infection		Verville et al. 1994

(*Continued over*)

Table 2 *Other bacteria*[a] *associated with hospital infection (Continued)*

Bacteria	Source and mode of spread	Circumstances of infection	Antibiotic characteristics of hospital strains	References
Nocardia asteroides	Inanimate environment; possibly air-borne spread from cases	Respiratory tract infection; immunosuppression		Houang et al. 1980; Javaly et al. 1992
Gram-negative bacteria				
Pseudomonas spp. and similar 'environmental' gram-negative bacilli	Water; damp areas; liquid medicaments; moist equipment; fecal carriage; direct and indirect contact (hands)	Colonization more frequent than infection. Chronic disease; renal failure; immune impairment; major surgery; burns; broad spectrum antibiotic treatment; neonates; implants; cannulae; catheters; respiratory equipment	Often multi-R	*Pseudomonas*
Burkholderia cepacia	Unsterilized aqueous solutions, e.g. disinfectants; nebulisers; patient-to-patient infection, probably air-borne	Various from solutions; late infection in cystic fibrosis	Often R to all classes	Pankhurst and Philpott-Howard 1996
Stenotrophomonas (Xanthomonas) maltophilia	Multiple epidemiological types; source and spread not clear	Bacteremia; device-related infections; broad spectrum antibiotics, including penems	Multi-R; characteristic R to penems	Vartivarian et al. 1994; Laing et al. 1995; Gerner-Smidt et al. 1995; Spencer 1995
Acinetobacter spp. (*A. baumannii*, *A. calcoaceticus*)	Endogenous; also indirect contact staff and equipment	Bacteremia; respiratory infection; ICUs; broad spectrum antibiotics	Increasingly multi-R	Bergogne-Berezin 1995; Mulin et al. 1995; Seifert et al. 1995
Achromobacter xylosoxidans		Uncommon bacteremia, respiratory infection	Aminoglycoside R and trimethoprim S typical	Schoch and Cunha 1988; Legrand and Anaissie 1992
Flavobacterium spp.		*F. meningosepticum* associated with infantile meningitis; others as *Pseudomonas* spp.	Often S to some antibiotics usually thought of as 'anti-gram-positive'	Ratner 1984
Aeromonas spp.		Bacteremia; soft tissue infection; outbreaks and invasive infection uncommon. Toxigenic strains may be enteritic		Mellersh et al. 1984; Murphy et al. 1995
Capnocytophaga spp.	Endogenous; usually from oropharynx	Bacteremia; immunosuppression, neutropenia	Aminoglycoside and trimethoprim R, β-lactam S typical	Kristensen et al. 1995

R, resistance; S, sensitivity.

a) Other than anaerobic gram-negative bacilli, *Legionella* spp., *S. aureus*, *Enterococcus* spp., *C. difficile*, *Mycobacterium* spp. and *P. aeruginosa*.

education programs, preferably working in tandem with infection control personnel.

Fungi and protozoa

Fungal infection continues to increase in hospitals (Pfaller and Wenzel 1992), as more effective and broader spectrum antibacterial agents and immunosuppressive regimens are deployed and increase the number of patients at risk. However, it remains likely that many fungal infections go undiagnosed because of a lack of awareness of risk factors and shortcomings in conventional laboratory techniques, e.g. fungemia is difficult to confirm microbiologically. As has recently been described in the HIV population, where *Candida dubliniensis* is now recognized as an important oral pathogen (Sullivan and Coleman 1998), studies combining molecular techniques and good epidemiology are likely to reveal a higher incidence of nosocomial infection and both new pathogens and new strains. The most common significant fungal isolate is *Candida albicans*, a bowel commensal that in most cases gives rise to endogenous infection. Members of other species, such as *Candida tropicalis*, *Candida parapsilosis*, *Candida krusei*, and *Candida glabrata*, are becoming more common. Their source is particularly associated with the skin, and therefore with intravascular cannulae. Less common fungi, such as *Fusarium* and *Trichosporon beigelii* are emerging causes of infection in cancer and bone marrow transplant recipients (Pfaller and Wenzel 1992). Clusters of infections with the same strain of *Candida* with evidence of colonization of the hands of staff, may occur under selective pressure from broad spectrum antibiotics (Burnie et al. 1985). Typing of *C. albicans* for epidemiological purposes is difficult. Phenotypic typing, such as biotyping, may be useful but DNA-based approaches are likely to be increasingly used. *Aspergillus* infection is related to the air-borne spread of spores, particularly when these reach high concentrations, as during building repairs near patients with neutropenia (Rogers and Barnes 1988) and occasionally other vulnerable groups, such as ICU patients (Humphreys et al. 1991). Molecular typing techniques allow the comparison of isolates from patients and the environment (Leenders et al. 1996). Clusters of infections due to non-*A. fumigatus* may indicate an environmental source (Loudon et al. 1996). Strategies for the prevention of aspergillus infection include pre-emptive antifungal therapy. Isolation of especially vulnerable patients in laminar flow ventilated facilities has been recommended.

There is no good evidence for the hospital spread of *Cryptococcus neoformans*. Phycomycetes may be transmitted to susceptible patients by dressings (Gartenberg et al. 1978) or by air (del Palacio Hernanz et al. 1983). Dermatophytes occasionally spread in geriatric units by close contact, or on clothing or apparatus (Peachey and English 1974).

The epidemiology of *Pneumocystis carinii* is obscure. Dormant infection has been said to be ubiquitous and reactivated by immune suppression, as may be infection by *Toxoplasma gondii*. On the other hand, air-borne spread of *P. carinii* can be shown in animals and there have been suggestions of clusters of linked cases (Rhame et al. 1984; Haron et al. 1988).

Cryptosporidium, a coccidian protozoon, is an important cause of debilitating diarrhea in the immunosuppressed, such as AIDS patients (Goodgame 1996). The oocysts are comparatively resistant to disinfection and may survive well in the inanimate environment. There is evidence of case-to-case spread and of transmission to staff and to other patients in hospitals (Martino et al. 1988), presumably by the fecal–oral route. A nosocomial outbreak in Denmark was linked to a ward ice machine (Ravn et al. 1991).

Scabies can be very disruptive in chronic institutions or hospital wards for the elderly (Holness et al. 1992). Infestation in patients with underlying skin disease or Norwegian scabies (extensive hyperkeratotic lesions) are especially contagious (Moberg et al. 1984). Early and reliable diagnosis, effective treatment, for example with permethrin, applied extensively to the body, and decontamination of bed linen and fomites are important to limit spread.

INVESTIGATION AND SURVEILLANCE OF INFECTION

Investigation of outbreaks

An outbreak is defined as two or more cases of symptomatic infection or of symptomatic infection and colonization, suspected on clinical or laboratory evidence. An outbreak may be obvious, such as a number of cases of acute diarrhea occurring in a ward over a few hours, or it may not be apparent for some time, such as deep staphylococcal infection after hip replacement in several patients over a period of months.

Outbreaks may be detected by simple laboratory surveillance with informal sources of clinical intelligence, but more subtle occurrences may be detected only by a more formal investigation. This should, at the same time, follow the epidemiological and the microbiological approaches. A first essential is definition of a case in clinical or microbiological terms. Outbreaks defined by an increase in the infection rate at a single body site may have a multiple bacterial etiology and the question arises whether there is in fact an outbreak. There may simply have been heightened awareness of infective episodes, a series of unlinked but significant clinical events, unrelated cases of infection by similar microorganisms or a ‘pseudo-outbreak’ due to specimen contamination (McGowan and Metchock 1996).

The spread of infection may be:

- from a point-source at one time
- from a point-source with continued exposure
- by person-to-person spread
- from infected persons with secondary contamination of the environment, or
- by a mixture of these.

Outbreaks should be defined epidemiologically in terms of time, place, and persons involved, and an epidemic curve should be plotted where the outbreak is relatively large (Palmer 1989). The shape of this curve and the microbiological cause may yield information for follow-up.

Small outbreaks purely of hospital concern may be dealt with by the Infection Control Team or equivalent (see Organization of hospital infection control) in association with clinical staff and local managers. More serious outbreaks and those with community implications require the involvement of those responsible for infection control in the community, i.e. local public health authorities and public health laboratories. When a major incident is found or suspected that is of potential seriousness for patients, or involves many patients or more than one hospital, or is liable to cause public concern, a formal action group or outbreak committee should be established (Hospital Infection Working Group of the Department of Health and Public Health Laboratory Service 1995). The responsibilities of such a group are to investigate and control the outbreak; to ensure that affected patients are adequately cared for, and that there are sufficient staff and supplies in the wards and laboratory; to disseminate information to patients, staff, relatives, and the general public; to record the episode, prepare a report, and to consider future prevention (Hospital Infection Working Group of the Department of Health and Public Health Laboratory Service 1995).

Depending on the nature of the outbreak (e.g. nosocomial legionellosis) or its extent (e.g. a large number of cases of hospital-acquired food poisoning), national bodies with specialized epidemiological skills such as the Health Protection Agency's Centre for Infections, Communicable Disease Surveillance Centre (UK) or Centers for Disease Control (USA) may need to be involved. Larger outbreaks, particularly those arising from a single source, whether or not microbiological indicators are available, may require formal epidemiological studies, particularly case-control studies (Rothman 1986; see also Epidemiology of infectious diseases). The descriptive epidemiology may have produced hypotheses to be tested. This approach may be more satisfactory than the use of extended case-control studies to investigate a variety of possible factors. However, case-control studies provide a powerful means to study some types of hospital outbreak and may give more rapid answers than microbiological methods, particularly if microbiological diagnosis of the particular infection is difficult or slow, e.g. some forms of viral gastroenteritis. Particularly in point-source outbreaks, 'cohort' studies (Rothman 1986) may be possible. In such studies, two or more groups that differ in exposure to a postulated source of infection may be compared for incidence of the infection. An example is the identification of the responsible food consumed in a food-borne outbreak. Such approaches are less useful in many hospital outbreaks that are due to person-to-person spread.

The increasing numbers of compromised hospital patients, the greater awareness of the hospital environment as a source and means of transmission of infection, and the emergence of more resistant microbes may require the use of considerable laboratory support to identify or confirm the extent of the outbreak and to confirm that preventive measures have been effective. The successful control of an outbreak requires good clinical investigation and in some instances up-to-date typing techniques such as ribotyping, polymerase chain reaction based techniques, etc. (Emori and Gaynes 1993; Wendt and Wenzel 1996).

Epidemiological typing

Epidemiological typing, characterization of isolates to intraspecies level, is useful (Parker 1978; Pitt 1994) to define the extent of an outbreak and to elucidate the sources and spread of infection and the effectiveness of prevention. Established typing methods that permit stable and discriminatory subdivisions are available for some common hospital pathogens, such as *S. aureus* (*Staphylococcus*). However, the continued appearance of new strains that are not typable by the existing systems, and the progress of newly significant species, diminish the value of classically established methods. This is a stimulus for the development of new methods, preferably those of more general applicability. The need is for simple, reproducible and discriminatory methods; fine discrimination can sometimes be attained by applying two or more typing methods sequentially. The aim is to define, with reasonable confidence, the strain responsible for an incident of infection by distinguishing all epidemiologically irrelevant isolates (Anderson and Williams 1956).

Well-established phenotypic methods of typing include serotyping, phage typing (including 'reverse' phage typing; de Saxe and Notley 1978), and bacteriocin typing. Methods in common use for more local studies include biotyping and comparison of antibiotic-sensitivity patterns, which is often the first clue to a common-source outbreak, but it is an unreliable epidemiological tool. Other methods that have proved to be of value for typing particular organisms include morphotyping of *C. albicans* (Brown-Thomsen 1968), the Dienes phenomenon for swarming strains of *Proteus* spp. (

Proteus, *Morganella*, and *Providencia*) and resistotyping (Elek and Higney 1970).

Analysis of DNA and other cellular constituents may provide a means of discriminating between strains that are similar by conventional typing methods, and makes possible the 'fingerprinting' of diverse species for which standard methods have not been established. The ease with which such methods can be applied has sometimes encouraged their use without proper critical evaluation of their suitability (Pitt 1994; Struelens et al. 1996). Electrophoretic analysis of cellular proteins (total cellular proteins, outer-membrane proteins, or essential enzymes) has been applied to several species, with discrimination by pattern recognition or automated mathematical analysis. Electrophoretic demonstration of plasmids, with or without treatment by restriction endonucleases, has been widely used (Mayer 1988). Chromosomal analysis is more difficult because of the larger size of the genome and the many fragments produced by endonuclease action. Pulsed field gel electrophoresis (PFGE) overcomes this problem by separating relatively few large-sized DNA fragments created by rare-cutting restriction endonucleases. PFGE has generally become the gold standard method for fingerprinting bacteria. Nucleic acid probes can also be applied to endonuclease digests (Bingen et al. 1994). The polymerase chain reaction can be used in a wide variety of ways to characterize the genome of microorganisms (van Belkum 1994). The various epidemiological typing and 'fingerprinting' methods have been recently reviewed elsewhere (Struelens 2002), and criteria for their use and evaluation were proposed by a Study Group of the European Society for Clinical Microbiology and Infectious Diseases (Struelens et al. 1996).

Surveillance

Surveillance is the systematic observation and recording of disease. It is an active process and implies the analysis and dissemination of data, so that direct or indirect action can subsequently be taken to improve patient care. Unlike the investigation of an outbreak or epidemic, surveillance is ongoing and the results can be used as an indicator of the quality of care, e.g. surgical wound infection rates (Glenister 1993; Smyth and Emmerson 2000). In his summary of the Proceedings of the First International Conference on Nosocomial Infections, Williams (1971) stated: 'Quite clearly, the first message from this conference is the need for surveillance. It is essential that hospital staff know what is going on in the hospital'. It is important to analyze surveillance activities critically to determine their usefulness in control, rather than to undertake them for their own sake, or with a false idea of their usefulness. The increasing availability of computer databases makes the analysis of data easier, but more traditional and time-consuming methods such as a card recording system can be used equally well. In particular, the use of optical scanning technology has been shown to improve the speed and accuracy of data entry and can greatly facilitate analysis and the dissemination of results (Smyth et al. 1997). In Britain, laboratory-based surveillance, with a variable degree of clinical reporting of infection, especially of organisms such as MRSA, has been the norm. In the USA, partly because of accreditation requirements and the fear of litigation, much staff time is devoted to the continuous gathering of data (Casewell 1980; Wenzel 1986). Justification for the latter approach comes from the Study of the Efficacy of Nosocomial Infection Control (SENIC) (Haley et al. 1985b). This large and expensive investigation determined the infection rates in 1970 and 1976, by a validated retrospective case-paper review, in a large sample of patients from 338 US hospitals. The rates were compared with the very variable infection control activities of the hospitals, expressed in terms of two indices, surveillance and control. The conclusion was that optimal measures would prevent 32 percent of hospital-acquired infections of the urinary tract, the lower respiratory tract, surgical wounds, and the bloodstream.

It should be recognized that comparisons of data collected, for example, in different institutions, are of limited value (Haley 1988). Even the most basic of surveillance activities, the detection of cases of hospital-acquired infection, is difficult and expensive, and many systems give results far below the actual rate. Furthermore, differences in case definitions between centers make reliable comparisons difficult. A comparison of different approaches, with a 'standard' of prospective identification, by an infection control physician who examined patients and records is shown in Table 3 (Freeman and McGowan 1981). Physician self-reporting is the least reliable method of recording infections. In the UK, Glenister (1993) assessed a number of different methods and compared these with a reference method. A laboratory-based telephone method took 3.1 h for every 100 beds, but was only 51 percent sensitive in detecting hospital-acquired infection, whereas a laboratory-based ward liaison method was 76 percent sensitive but more time-consuming.

The dissemination of the results of surveillance is crucial if a beneficial effect on patient care in the form of improved practices and reduced hospital-acquired infection rates are to result. Wound infection rates should be reported to individual surgeons (Cruse et al. 1980). The prevalence of all types of nosocomial infection fell from 10.5 to 5.6 percent over a period of 3 years following surveillance in the form of repeat prevalence surveys accompanied by improvements in infection control policies (French et al. 1989).

It is not always feasible to conduct unit or hospital-wide surveillance. Consequently, targeted or selective surveillance is recommended (Hospital Infection Working Group of the Department of Health and Public

Table 3 *Hospital-acquired infection: sensitivity of methods of case finding*

Method	Sensitivity
Physician self-report forms	0.14–0.34
Fever	0.47
Antibiotic use	0.48
Fever plus antibiotic use	0.59
Microbiology reports	0.33–0.65
Selected chart review with 'Kardex' clues	0.85
Total chart review	0.90
SENIC pilot project	
Prospective data collection	0.52–0.90
Retrospective chart review	0.66–0.80
Standard method	1.00

SENIC, Study on the Efficiency of Nosocomial Infection Control. Standard method, clinical detection of infection by a trained physician, who examined all the patients and reviewed all the data in respect of them, is given a sensitivity of 1.00 by definition. Modified from Freeman J., McGowan J.E. 1981. *Rev Infect Dis*, **3**, 658 (© The University of Chicago) with permission.

Health Laboratory Service 1995; Glynn et al. 1997). Targeted surveillance concentrates on areas where infection is particularly important and where it has a major impact on patient morbidity and mortality, e.g. intensive care and oncology units (Hanberger et al. 2001). Selective surveillance addresses problem areas or units or specialties with potential problems, outside the occurrence of a clearly defined epidemic, where infection rates might be higher than expected, or following the opening of a new specialist unit or facility. As the duration of hospital stay becomes shorter, it is important not to underestimate hospital infection presenting in the community after discharge. With the availability of newer typing techniques (see above), it should become easier to trace the spread of organisms that cause nosocomial infection so that preventive strategies to reduce crossinfection may be based on clearer scientific evidence. The continuing challenge for infection surveillance schemes is to give ownership of infection prevention to clinicians. Surveillance systems need to be cognizant of the time restraints and consequent issues surrounding compliance with data collection. It is therefore important that minimum datasets are used wherever possible to facilitate the process of surveillance. The mandatory *S. aureus* bacteremia scheme in England and Wales referred to above (see Bacteremia) is an example of how a simple collection system can provide easily accessible data, which in turn should allow hospitals to focus resources on problem areas and then monitor the effects.

ORGANIZATION OF HOSPITAL INFECTION CONTROL

Systems for the management of infection control in hospitals developed in parallel in Great Britain and in the USA, and essentially similar systems have been adopted in other European countries and in other parts of the world (Hambraeus 1995; Astagneau and Brucher 2001; Bassetti et al. 2001; Bijl and Vos 2001; Frank et al. 2001; Hryniewicz et al. 2001; Jepsen 2001; Lim 2001; Reybrouck et al. 2001; Rodriguez-Bano and Pascual 2001; Leblebiciogh and Unal, 2002; Melo-Cristino et al. 2002; Reed et al. 2003).

In the UK, the staff who provide infection control expertise in hospitals have been reviewed and guidance has been issued (Hospital Infection Working Group of the Department of Health and Public Health Laboratory Service 1995). Executive action in infection control, though a responsibility of the chief executive (CE) of the unit, is the function of an infection control team (ICT), which must maintain close liaison with the CE, or appointed deputy, and other managers. In its simplest form the ICT consists of an infection control doctor (ICD) and an infection control nurse (ICN) (Gardner et al. 1962). The ICD is the control of infection officer (Colebrook 1955; Subcommittee of the Central Health Services Council 1959) and the leader of the team, and may be formally appointed with responsibility to the medical consultants' committee or to the CE, and may report directly to the Strategic Health Authority or Primary Care Trusts. The ICT may be augmented by the active participation of medical microbiologists, infectious disease physicians, scientists, medical laboratory scientific officers, and others, and should be supported by an Infection Control Committee (ICC) (Hospital Infection Working Group of the Department of Health and Public Health Laboratory Service 1995).

The ICD has a wide-ranging role in hospitals and is the specialist adviser on hospital infection to the executive officers of hospital trusts and to managers and planners. The ICD is expected to develop an infection control program, policies, and procedures and to ensure that all staff are educated in infection control and that suitable audit is carried out. The ICD has the primary responsibility for surveillance and the investigation of outbreaks and advises about infectious disease in hospital staff and its prevention, including immunization policy. The ICD is the leader of the ICT and works closely with and supports the ICN. In the USA, the equivalent is the infection control epidemiologist.

The ICN is responsible for infection control matters to the ICD and undertakes similar activities either with the ICD or independently under his or her general guidance. The ICN may provide clinical surveillance, day by day and in outbreaks, and has particular responsibility for the application of policies and procedures and for the training of staff. The ICN often has close links with various ancillary departments, such as the pharmacy, domestic services, laundry, etc. The counterpart of the ICN in the USA is the infection control practitioner (Goldmann 1986). On 5 December 2003, Sir Liam Donaldson the Chief Medical Officer of England

announced wide ranging proposals in an attempt to reduce the burden of healthcare-associated infections. The plan, 'Winning Ways: Working together to reduce Healthcare Associated Infection in England' means that every NHS trust will get a designated director of infection control – a senior figure with experience in the discipline with the power to impose tough new rules on each hospital in order to reduce infection levels. He or she will lead dedicated infection control teams, charged with ensuring every possible step is taken to minimize the risk of infection. In addition, the NHS watchdog, the Healthcare Commission, will be asked to make infection control a key priority when assessing hospital performance.

The infection control link nurse

All healthcare workers need to ensure that effective infection control practices are implemented in the care of patients to achieve a reduction in healthcare-associated infection. It is important for wards and directorates to develop 'ownership' of infection control. One way of assisting this is by the use of infection control link nurses (ICLN) who have been implemented by infection control teams (ICT) as a method of improving practice at a clinical level (Cooper 2001; Dawson 2003).

ICLNs are a link or intermediary between the clinical areas/wards and ICTs. A key part of their role is to provide information to assist in the early detection of outbreaks of infection and to help increase awareness of infection control issues on their ward. Attention should be drawn to ICNs of changes of practice and equipment which could have implications for infection control (Hospital Infection Working Group, Department of Health and Public Health Laboratory Service 1995; Comptroller and Auditor General, National Audit Office 2000). In some trusts they have been trained to collect surveillance data on healthcare-associated infections for the ICT (Teare and Peacock 1996). It is essential that they have sufficient clinical experience and standing to have authority with managers and colleagues. ICLNs should not be seen as a substitute for the ICN, they are a ward-based resource who act under the supervision of the ICNs as a role model for colleagues. The ideal ICLN should be a keen, enthusiastic, motivated volunteer with a special interest in infection control (Charalambous 1995). The role of ICLNs is one that is still evolving. Many trusts have used them with success and they have been of particular value in the light of controls assurance and clinical governance (Hill et al. 2001). It is important for infection control to become the responsibility of directorates and the use of ICLNs at ward level can assist with this.

The ICC, which includes the augmented ICT, together with representatives of clinical departments and service departments, is not to be confused with the Outbreak Committee (OC), but is usually the body for discussing, monitoring, and approving the activities of the ICT listed above and lends it authority. It produces an action plan for infection control. It also produces general policies, encourages education, and reviews the implementation of the measures (Jenner and Wilson 2000; Naikoba and Hayward 2001).

It is important that the hospital ICT should have strong links with the community. This connection has been responsible for preventing many outbreaks of infection both in hospitals and outside. The consultant for communicable disease control (CCDC) has a general responsibility for infection control in the whole district and provides the main communication channel for the hospital ICT on such matters. In major outbreaks with implications wider than the hospital unit both the ICD and the CCDC will be actively involved. In outbreaks of typical nosocomial infection mainly restricted to hospital patients the ICD will lead the OC, with information to the CCDC.

The present arrangements for infection control in England and Wales were reviewed by Howard (1988) for the Hospital Infection Society and of the 207 Health Districts and London postgraduate hospitals approached, 93 percent responded. They were responsible for 95 percent of 'acute' hospital beds and 85 percent of other beds. Their replies identified 264 ICDs, of whom 82 percent were medical microbiologists; ICCs had been established in 92 percent of districts; 205 ICNs were in post and 93 percent of these worked closely with a medical microbiologist who was usually the ICD.

Thus the ICT, however constituted, has responsibility for the investigation of untoward occurrences and, even more importantly, for establishing microbiologically safe conditions in the hospital, for the provision of necessary supplies, and for ensuring safe practices in the day-to-day care of patients. Written statements of policies and procedures must be provided; the ICC and ICT must oversee the implementation of these and the education of staff in their use and interpretation. For detailed recommendations, the reader is referred to reviews (Bennett and Brachman 1992; Wenzel 1993; Philpott-Howard and Casewell 1994; J. Wilson 1995). Individual procedures may be required for special units, e.g. neonatal, pediatric, obstetric, intensive therapy, dialysis, transplantation, and oncology. In addition infection control is now an important part of risk management (Farrington and Pascoe 2001) and clinical governance (Masterton and Teare 2001).

Matters to be dealt with, in many cases in liaison with other groups of staff, are listed in Table 4.

In spite of the uniformity of approach to infection control in Europe, practices are diverse, as was revealed during a survey of infection in intensive care units (Vincent et al. 1995). In the USA and in Europe, there is an increasing movement towards providing and

Table 4 *General subjects for which infection control policies may be required*

Requirements
Provision of safe air supply (to operating theaters and accommodation for immunosuppressed patients)
Safe provision of water and food
Cleaning and general hygiene
Pest control
Waste disposal
Laundry
Decontamination (cleaning, disinfection, sterilization) of all equipment and materials
Ward procedures, including dressings and minor invasive procedures, urinary catheterization
Disposal of excreta
Venepuncture and vascular cannulation
Operating theater procedures
Antibiotic use, including prophylaxis
Isolation of patients and 'barrier nursing', to prevent spread of infection ('source isolation') or to protect susceptibles ('protective isolation')
Notification of infective disease and other liaison with community officers
Laboratory and pharmacy procedures
Staff health, immunization, and carriage of pathogenic microorganisms

unifying standards in hospital infection control against which practice can be judged and audit can be carried out (Infection Control Standards Working Party 1993; Cookson 1995; Jepsen 1995; McGowan 1995). It has been suggested that these should be 'outcome' rather than 'process' oriented (McGowan 1995). Although the methods available for measuring health benefit are limited, improving the health of the population by reducing the morbidity, mortality, and use of resources incurred by healthcare-associated infection must remain the aim of all the systems outlined above (Ward et al. 1997; Plowman et al. 1999; Comptroller and Auditor General, National Audit Office 2000). The National Audit Office has recently reviewed the extent of progress in the delivery of infection control in England since its original 2000 report (Comptroller and Auditor General, National Audit Office, 2004).

Microbial susceptibility and resistance to chemical and physical agents

A. DENVER RUSSELL

Introduction 1
Chemical agents used in antisepsis, disinfection, preservation, and sterilization 1
Physical agents and other sterilization methods 25
References 35

INTRODUCTION

Chemical and physical agents have, in one form or another, been used for many centuries to destroy microorganisms. In ancient times, methods were empirical and it is only within the last 150 years or so that a scientific basis for them has been developed and their applications expanded. Early studies, considered in part by Hugo (1991a, 1999a) and Block (2001a), form the basis of the scientific consideration of antisepsis, disinfection, preservation, and sterilization.

This chapter will consider various types of chemical and physical agents, their medical and other uses, and the mechanisms of both microbial inactivation and microbial resistance. Because the subject area is so vast, appropriate review articles will be cited frequently together with salient research papers when necessary.

CHEMICAL AGENTS USED IN ANTISEPSIS, DISINFECTION, PRESERVATION, AND STERILIZATION

There are several types of chemical antimicrobial agents (for chemical structures, see Russell and Chopra 1996; Hugo and Russell 1999; Russell et al. 1999). They have a variety of uses, both medical and otherwise; their activity is influenced by many factors (physical, chemical, and biological); their efficacy may be evaluated by various techniques; and their mechanism of action varies from one type of chemical to another.

Terminology

Several important terms (see also BSI 1991; Block 2001b) are in regular use, including the following:

- *Sterilization*: the destruction or removal (by filtration) of all microorganisms.
- *Disinfection*: the destruction of most microorganisms, but not usually bacterial spores. Usually applied to the treatment of inanimate objects, it can also refer to the disinfection of the skin, e.g. before an operation. In some countries, a disinfectant is considered to be a substance that will also destroy bacterial spores.
- *Antisepsis*: the destruction or inhibition of microorganisms on living tissues, thereby limiting or preventing the harmful effects of infection.
- *Preservation*: the prevention of multiplication of microorganisms in formulated products (e.g. food, pharmaceuticals, cosmetics), thereby preventing spoilage or contamination, which could render the product a possible hazard to the consumer.

Other terms are more specific, e.g. those having the suffix 'stat' or 'cide.' A static agent, e.g. bacteriostat, fungistat, or sporistat, inhibits the growth of bacteria or fungi or germination of spores, respectively, whereas a cidal agent, e.g. bactericide, fungicide, sporicide, or virucide, kills bacteria, fungi, spores, or viruses, respectively. The general term 'biocide' refers to a chemical (nonantibiotic) agent that inactivates microbes. The term 'chemosterilant' (or sometimes 'chemosterilizer' or

'sterilant') is used to describe a chemical agent that is used to kill all microorganisms, including spores (Block 2001b).

Types and uses of chemical agents

Antimicrobial agents are widely used for many purposes (Table 1). Comprehensive data are provided by Gardner and Peel, (1991), Ayliffe et al. (1993), Gould (1995), Rutala (1990, 1995), McDonnell and Russell (1999), Russell (1999a, b, c, d, e), and Block (2001b). Fraise (1999) describes factors influencing the choice of hospital disinfectants, Coates and Hutchinson (1994) consider the relevant aspects of a suitable hospital disinfection policy and Rutala and Weber (1999a, b), the role of disinfection and sterilization in infection control, and the disinfection of endoscopes.

PHENOLS, BISPHENOLS, AND CRESOLS

Most phenols used as disinfectants are obtained from tar, a byproduct in the destructive distillation of coal. Fractionation of the tar yields a group of products including phenols (tar acids). A coal tar produced in a low-temperature carbonization process contains (in parentheses, boiling range in °C) phenol (182), cresols (189–205), xylenols (210–230), and high-boiling tar acids (230–310). The combined fraction of cresols plus xylenols is also available commercially as cresylic acid. Noncoal tar phenols are also available, e.g. 2-phenylphenol (*o*-phenylphenol). Phenol itself is now made in large quantities synthetically, as are some of its derivatives (Hugo and Russell 1999).

Para (4)-substitutions in phenols of an alkyl chain up to six carbon atoms in length increase antimicrobial activity. Activity is also improved by halogenation and by a combination of alkyl and halogen substitution; greatest activity is achieved when the alkyl group is in the *ortho*(2) and the halogen *para*(4) positions in relation to the phenolic group. Nitration also increases antimicrobial potency but unfortunately also enhances systemic toxicity; nitrophenols act as uncoupling agents and interfere with oxidative phosphorylation. Phenols are more active in the undissociated forms at acid than at alkaline pH (Russell and Chopra 1996; Hugo and Russell 1999).

Phenols and cresols are bactericidal to gram-positive and gram-negative bacteria, but bacterial spores are resistant at ambient temperatures. 2-Phenylphenol and the black fluids (see below) are particularly effective against mycobacteria, but bisphenols are ineffective. Phenols and cresols, especially when halogenated, possess antifungal activity. Lipid-enveloped viruses may be sensitive to phenolics whereas nonenveloped viruses are more resistant: 2-phenylphenol is active against both types. Triclosan (2,4,4′-trichlor-2′-hydroxydiphenylether) is a chlorinated phenylether (sometimes referred to as a bisphenol) used in some medicated soaps and hand-cleansing gels and as a body wash; it is predominantly bacteriostatic rather than bactericidal, but has a broad spectrum of activity, except for *Pseudomonas aeruginosa* (Schweizer 2001). Hexylresorcinol (HCP) is active mainly against gram-positive bacteria (Russell and Chopra 1996).

Black fluids consist of a solubilized crude phenol fraction prepared from tar acids (boiling range 250–310°C). On dilution with water, black fluids give either clear solutions or emulsions. White fluids consist of emulsified phenolic compounds. On dilution with water, they form weaker emulsions and are more stable in the presence of electrolytes than are black fluids.

ACIDS, ACIDULANTS, AND ESTERS

Many aliphatic and aromatic acids are employed as preservatives, especially in the food industry, and to some extent in pharmaceutical and cosmetic products. They include acetic, benzoic, propionic, and sorbic acids and the methyl, ethyl, propyl, and butyl esters (the parabens) of *para*(4)-hydroxybenzoic acids. They are not sporicidal and the activity of the acids, but not the esters, is very pH-dependent, since activity is associated mainly with the undissociated form. Acids may be added to various foods as acidulants, notably the organic lipophilic acids (benzoic, sorbic, propionic) referred to above. Organic acids of chain length greater than C_{10} or C_{11} are highly effective against gram-positive but not against gram-negative bacteria (Russell and Gould 1988), but their low solubility restricts their use (Sofos and Busta 1999). Lactic acid, an acidulant exhibiting preservative activity, is the main product of many food fermentations.

Citric acid is an approved disinfectant against foot-and-mouth virus. Lactic acid, CH_3-CH(OH)COOH, has been employed as an aerial disinfectant against nonsporing bacteria. Formic acid, HCOOH, and propionic acid have been used for controlling salmonellae in feedstuffs. Two mineral acids employed in veterinary work are hydrochloric and sulfuric acids. The former, but not the latter, is sporicidal and has been used at a concentration of 2.5 percent for disinfecting hides and skin contaminated with anthrax spores. In some countries, a 5 percent solution of sulfuric acid has been used, usually in combination with phenol, for decontaminating floors, feed boxes, and troughs (Russell and Hugo 1987).

ALKALIS

The antimicrobial action of alkalis is related to hydroxyl ion concentration. Sodium hydroxide (caustic soda, lye, soda lye, NaOH) possesses strong alkali properties. It kills most common vegetative bacteria and high concentrations (5 percent and above) are lethal to anthrax spores. Calcium hydroxide (hydrated lime, air-slaked

Table 1 *Summary of uses of some antimicrobial agents*

Group	Use(s)	Example(s)
Acids and esters	Preservation	Organic acids, parabens
	Aerial disinfection	Lactic acid
	Veterinary disinfection	Hydrochloric, sulfuric, citric acids
	Salmonella control in feedstuffs	Formic acid, propionic acid
Alcohols	Working surfaces, equipment, gloved hands (rapid action)	Ethanol, isopropanol
	Preservation	Bronopol, ethanol
Aldehydes	Disinfection/sterilization of thermolabile medical equipment	Glutaraldehyde, succinaldehyde-based products, orthophthalaldehyde
	Virucide in preparation of some human and veterinary vaccines; removal of warts; antiseptic mouthwash	Formaldehyde solution
	Topically; irrigation solutions; treatment of peritonitis	Formaldehyde-releasing agents, e.g. noxythiolin, taurolin[a]
	Cosmetic preservatives	Formaldehyde-releasing agents, e.g. imidazole derivatives
Alkalis	Vehicle disinfection	Sodium carbonate, trisodium phosphate
	Whitewashing surfaces	Calcium hydroxide
Alkylating agents	See Vapor-phase disinfectants	Ethylene oxide, propylene oxide, β-propiolactone
Amphoteric surfactants	Skin 'disinfection;' disinfection of surgical instruments; sanitizers and disinfectants in food industry	Dodecyl-di(aminoethyl)-glycine derivatives
Antibiotic	Food preservative	Nisin
Biguanides	Antiseptic, disinfectant, preservative in some ophthalmic products; antiplaque agent; veterinary teat dip	Chlorhexidine, alexidine
	Swimming-pool disinfection; application to surfaces in food industry; preservation of leather	Polyhexamethylenebiguanide (PHMB), a polymeric biguanide
Bisphenols	Surgical scrubs; medicated soaps; limited uses as preservative in cosmetics	Hexachlorophane
	Surgical scrubs; soaps; deodorants; hand-cleansing gels	Triclosan
Diamidines	Topical application to wounds	Propamidine, dibromopropamidine, as isethionates
Halogen-releasing agents	Disinfection of blood spillages containing HIV or HBV; industrial sanitizing compounds (food, dairy, restaurant, swimming pool); veterinary disinfection	Hypochlorites, dichloro- and trichloro-isocyanuric acids
	Disinfection of hands preoperatively; antiseptics; cleansing of dairy plant; veterinary teat dip	Iodophors (including povidone–iodine)
Heavy-metal derivatives	Algicides; fungicides; wood, paint, cellulose and fabric preservation	Copper derivatives
	Fungicides; bactericides; textile and wood preservation	Organotin compounds
	Pharmaceutical preservation	Organomercurials
	Prevention of infection in burns	Silver nitrate, silver sulfadiazine
Isothiazolones	Preservatives for cosmetics, toiletries and pharmaceuticals, fabrics	Mixture of chloromethyl and methyl derivatives
Peroxygens		
	Oxidizing agent used as antiseptic and disinfectant	Hydrogen peroxide
	Disinfection/chemosterilization of endoscopes	Peracetic acid
Phenols and cresols	Preservation	Phenol, cresol, chlorocresol
	Disinfection	Black fluids, white fluids
	Aerial disinfection	Hexylresorcinol
	Food preservatives	Phenolic antioxidants, e.g. butylated hydroxyanisole, butylated hydroxytoluene

(*Continued over*)

Table 1 *Summary of uses of some antimicrobial agents (Continued)*

Group	Use(s)	Example(s)
Quaternary ammonium compounds	Preoperative disinfection, bladder and urethra irrigation, ophthalmic preservation, skin disinfection, oral and pharyngeal antisepsis, cosmetic preservation of emulsions	Cetrimide, benzalkonium chloride, cetylpyridinium chloride (as appropriate)
Sulfites and nitrites	Food preservation	Sodium metabisulfite, sodium nitrite (carcinogenic?)
Vapor-phase disinfectants	Medical and pharmaceutical sterilization	Ethylene oxide
	Disinfection/sterilization of heat-sensitive materials	Low-temperature steam with formaldehyde
	Veterinary fumigation	Formaldehyde
	Decontamination	β-Propiolactone (carcinogenic?)
	Surface sterilization	Hydrogen peroxide (vapor phase)
	Range of disinfection and sterilization purposes	Ozone

HBV, hepatitis B virus; HIV, human immunodeficiency virus.
a) There is some doubt as to whether taurolin acts as a formaldehyde releaser.

lime, $Ca(OH_2)$) is produced and heat is generated when calcium oxide (lime, quicklime, CaO) is moistened with water. As a 20 percent suspension, calcium hydroxide is effective for whitewashing surfaces, which kills most types of nonsporing bacteria. Sodium carbonate (Na_2CO_3) is used primarily as a cleaning agent, a 4 percent w/v solution being used for washing vehicles before disinfecting them after a shipment of animals. It has also been used extensively as a cleaning agent in outbreaks of foot-and-mouth disease. Trisodium phosphate (Na_3PO_4) has similar properties and uses. Comprehensive data on the veterinary uses of alkalis are provided by Huber (1982) and Linton et al. (1987).

CHLORINE-RELEASING AGENTS

The stability of free available chlorine in solution depends upon a number of factors, in particular chlorine concentration, pH, presence of organic matter, and light (Dychdala 2001).

Hypochlorites and organic *N*-chloro compounds are the two most widely used types of chlorine-releasing agents (CRAs). The hypochlorites have a wide antimicrobial spectrum and are among the most potent sporicidal agents. They are active against enveloped and nonenveloped viruses (Springthorpe and Sattar 1990; Sattar et al. 1994; Maillard 2001; Prince and Prince 2001) but at one time were considered to be rather ineffective against mycobacteria (Croshaw 1971). More recent studies demonstrate, however, that they are mycobactericidal (Favero and Bond 1993; Dychdala 2001).

Two factors with pronounced effects on their antimicrobial action are (a) the presence of organic matter, chlorine being highly reactive; and (b) pH, the hypochlorites being more active in acid than in alkaline conditions: the active factor is undissociated hypochlorous acid, HClO (Dychdala 2001). Hypochlorite solutions gradually lose strength on storage, so fresh solutions must be prepared before use. Methanolic solutions buffered to pH 7.6–8.1 appear to show maximal stability and sporicidal activity and are worthy of further investigation. In addition to their medical uses, hypochlorites are used widely in the dairy industry and as disinfectants of farm buildings, e.g. for concrete floors, walls, and ceilings (Linton et al. 1987). Sodium hypochlorite is normally used for the disinfection of swimming pools.

N-chloro compounds, containing the =N–Cl group, possess microbicidal activity; they include chloramine T, dichloramine, halazone, and the sodium salts of dichloroisocyanuric (NaDCC) and trichloroisocyanuric acids. All appear to hydrolyze in water to produce an imino (=NH) group. Their action is slower than that of the hypochlorites, but this can be increased under acidic conditions. The disinfecting action of chloramine decreases less significantly than that of the other compounds in the presence of organic matter, and it has been used in veterinary practice for washing and spraying surfaces and for soaking items to be decontaminated. The uses of chlorine compounds are summarized in Table 1. NaDCC has been recommended as a disinfectant for use against various body spillages from acquired immune deficiency syndrome (AIDS) patients (Bloomfield et al. 1990; Bloomfield 1996; Dychdala 2001; Prince and Prince 2001).

Chlorine dioxide, a recently introduced instrument disinfectant (Knapp and Battisti 2001; McDonnell 2001), is more active than the hypochlorites at alkaline pH and in the presence of organic matter, although its activity may be reduced under dirty conditions. It is sporicidal, bactericidal, mycobactericidal (including activity against glutaraldehyde-resistant *Mycobacterium chelonae* strains), and fungicidal (Fraise 1999; Griffiths et al. 1999).

SUPEROXIDIZED WATER

Superoxidized water contains a mixture of oxidizing substances, the presence of hypochlorous acid probably contributing to a marked degree to its mechanism of action (Rutala and Weber 2001a, b). It is prepared by the electrolysis of saline solutions, the end product being water. It is rapidly microbicidal to a range of microorganisms in the absence (Selkon et al. 1999) and presence (Shetty et al. 1999) of serum, although activity against *Clostridium difficile* spores is greatly reduced (Shetty et al. 1999).

IODINE AND IODOPHORS

Iodine was first employed for the treatment of wounds some 150 years ago. Normally it is used in aqueous or alcoholic solution but it is only sparingly soluble in cold water; solutions can be made with potassium iodide. Iodine is an efficient microbicidal agent rapidly lethal to bacteria and their spores, molds, yeasts, and viruses. Antiseptic-strength iodine solutions are not sporicidal (Russell 1990a, b; Favero and Bond 1993). Iodine is less reactive than chlorine but, whereas the activity of high iodine concentrations is little affected by the presence of organic material, that of low concentrations is significantly reduced. The activity of iodine is greater at acid than at alkaline pH; the most active form is diatomic iodine (I_2). At acid and neutral pH, hypoiodous acid (HIO) is less bactericidal. At alkaline pH, hypoiodite ion (HIO^-) is even less active and iodiate (IO_3^-), iodide (I^-), and triiodide (I_3^-) ions are all inactive (Trueman 1971; Bloomfield 1996).

Because iodine has certain limitations in use, namely toxicity and staining of fabrics, attention has been turned towards the iodophors (literally, 'iodine carriers'), solutions in which iodine is solubilized by surface-active agents and that retain the microbicidal, but not the undesirable, properties of iodine (Bloomfield 1996). In most iodophor preparations the carrier is usually a nonionic surfactant, whereas in poloxamer iodine formulations the carriers are poloxamers, a series of nonionic polyoxethylene–polyoxypropylene polymers. When an iodophor is diluted with water, dispersion of the micellar aggregates of iodine occurs and most of the iodine is liberated slowly (Gottardi 1985). Dilutions of commercial povidone–iodine solutions may be more bactericidal (Berkelman et al. 1982) or sporicidal (Williams and Russell 1993) than undiluted stock solutions. The reasons are complex but iodine complexation is involved since the concentration of free iodine (I_2) determines activity (Gottardi 1985).

The iodophors are microbicidal with activity over a wide pH range. Provided that the pH does not rise above about 4, iodophors retain their antimicrobial potency in the presence of organic matter. There is a pronounced decrease in activity if solutions are diluted excessively with water that has a high alkaline hardness. The presence of a surface-active agent as carrier improves the wetting capacity. Iodophors are used in the dairy industry; when employed in the cleansing of dairy plant, it is important to keep the pH acidic with phosphoric acid, to ensure adequate removal of milkstone (dried residue of milk). They are also used for skin and wound disinfection. In some countries, alcoholic solutions of iodophors are widely used for disinfection of operation sites. In the veterinary context, iodophors formulated with phosphoric acid are employed as antiseptics, disinfectants, and teat dips (Huber 1982; Russell and Hugo 1987).

SURFACE-ACTIVE AGENTS

Surface-active agents (surfactants) have hydrophobic and hydrophilic regions in their molecular structure. On the basis of the charge or the absence of ionization of the hydrophilic group, these surfactants are classified into anionic, cationic, nonionic, and ampholytic (amphoteric) compounds.

Nonionic surfactants are not antimicrobial, but low concentrations of polysorbates (Tweens) are claimed to affect the permeability of the outer membrane of gram-negative bacteria (Brown 1975). High concentrations, however, neutralize the activity of some types of antimicrobial agents (Russell et al. 1979; Russell 1999a). *Anionic surfactants* usually have strong detergent but weak antimicrobial properties, except at high concentrations, which induce lysis of gram-negative bacteria (Salton 1968). Fatty acids are considerably more active against gram-positive than gram-negative organisms (Russell and Gould 1988).

Amphoteric agents combine the detergent properties of anionic with the antimicrobial properties of the cationic compounds. Activity remains virtually constant over a wide pH range and they are inactivated less readily than cationic surfactants by proteins. Examples of amphoteric surfactants are the Tego series of compounds (Hugo and Russell 1999).

For microbiological use, most important surface-active agents are the *cationic surface-active agents*, quaternary ammonium compounds (QAC) (Hugo and Russell 1999; Merianos 2001). They possess strong bactericidal but, at normal in-use concentrations, weak detergent properties. QACs may be considered as organically substituted ammonium compounds in which the nitrogen atom has a valency of five; four of the substituent radicals (R^1–R^4) are alkyl or heterocyclic and the fifth is a small anion. The sum of the carbon atoms in the four R groups is greater than ten. For a QAC to have high antimicrobial activity, at least one of the R groups must have a chain length in the range C_8–C_{18} (Hugo and Russell 1999). The QACs are primarily active against gram-positive, nonsporing bacteria; at high concentrations they are lethal to gram-negative organisms, although *P. aeruginosa* tends to be particularly resistant (Russell 1999a).

They are sporostatic but not sporicidal, and fungistatic rather than fungicidal. They are active against viruses with lipid envelopes, e.g. herpes and influenza, but are much less so against nonenveloped viruses, e.g. enteroviruses (Narang and Codd 1983; Resnick et al. 1986). A newer QAC product is claimed to have mycobactericidal activity (Nicholson et al. 1995) but no neutralizing agent was included in the test methodology.

The QACs are incompatible with a wide range of chemical agents, including nonionic and anionic surfactants, and phospholipids such as lecithin. Use is made of this property in evaluating the lethal effects of QACs by employing a combination of lecithin and a nonionic surfactant as a neutralizing agent (Russell et al. 1979). Antimicrobial activity is affected greatly by organic matter and by pH. Activity is greater in alkaline conditions because there is an increase in the degree of ionization of bacterial surface groups so that the cell surface becomes more negatively charged.

Organosilicon-substituted quaternary ammonium salts, organic amines, or amine salts with antimicrobial activity in solution are also highly effective on surfaces. One such, 3-(trimethoxysilyl)propyloctadecyldimethyl ammonium chloride, exhibits powerful antimicrobial activity while chemically bonded to a variety of surfaces (Malek and Speier 1982; Speier and Malek 1982). Uses of the QACs are summarized in Table 1.

BIGUANIDES AND POLYMERIC BIGUANIDES

The most important member of the family of N^1,N^5-substitued biguanides is chlorhexidine, which is available as dihydrochloride, diacetate, and gluconate, the last-named being the most water-soluble. Chlorhexidine has a wide spectum of activity against gram-positive and gram-negative bacteria but is not sporicidal or mycobactericidal; it is also generally considered as having a low activity against fungal spores and viruses (Russell and Day 1993; Ranganathan 1996; Hugo and Russell 1999; Russell 1999a, c; Denton 2001). Potency is reduced in the presence of serum, blood, pus, and other organic matter. Because of its cationic nature, activity is also reduced in the presence of soaps and other anionic compounds. Chlorhexidine is more active at alkaline pH because an increase in the degree of ionization of bacterial surface groups renders the cell surface more negatively charged (Hugo 1999b). The main uses of chlorhexidine are as a medical, dental, and veterinary antiseptic, as a disinfectant, and as a preservative in some types of pharmaceutical products (Russell and Day 1993).

Alexidine differs from chlorhexidine in that it posesses ethylhexyl end groups (Russell and Chopra 1996); it is also more rapidly bactericidal and produces a significantly faster alteration in bacterial permeability (Chawner and Gilbert 1989a,b).

Vantocil is a heterodispersed mixture of polyhexamethylene biguanides (PHMB) with a molecular weight of approximately 3 kDa. It is active against gram-positive and negative bacteria (*P. aeruginosa* and *Proteus vulgaris* are less sensitive) but is not sporicidal. Because of the residual positive charges on the polymer, PHMB is precipitated from aqueous solutions by anionic compounds. The activity of PHMB increases with increasing polymer lengths but synergistic effects have been observed in a mixture of polymeric biguanides (Gilbert et al. 1990a, b).

DIAMIDINES

The aromatic diamidines are organic cationic agents that show antimicrobial activity (Hugo 1971). The two most important members are propamidine (4,4′-diamidinophenoxypropane) and the more active dibromopropamidine, both used as the soluble isethionate salts. Gram-positive bacteria are considerably more sensitive than gram-negative organisms and activity decreases at acid pH and in the presence of organic matter. Bacteria cultured in the presence of increasing doses of a given diamidine rapidly acquire resistance to it and to other diamidines (Hugo 1971). The past decade or so has seen the isolation of multiple antibiotic-resistant strains of *Staphylococcus aureus* (Townsend et al. 1984) and *S. epidermidis* (Leelaporn et al. 1994), which possess plasmid-mediated resistance to cationic agents, including propamidine.

ALDEHYDES

Three aldehydes are important, namely the monoaldehyde, formaldehyde (methanal), and two dialdehydes, glutaraldehyde (pentane-1,5-dial) and *ortho*-phthalaldehyde, although other alkdehydes, e.g. succinaldehyde, also possess antimicrobial activity.

Formaldehyde

Formaldehyde (CH_2O) is employed in the liquid and vapor states; use of the latter is described below (see section on Gaseous and vapor-phase disinfectants).

Formaldehyde solution (formalin) is an aqueous solution containing 34–38 percent w/w of formaldehyde (CH_2O). The presence of methyl alcohol (methanol, CH_3OH) delays polymerization. Formaldehyde is lethal to bacteria and their spores (but less so than glutaraldehyde), fungi, and viruses. It combines readily with proteins and is less effective in the presence of organic matter. Formaldehyde is employed as a virucidal agent in the preparation of many human and veterinary vaccines (Russell and Hugo 1987), as an antiseptic mouthwash, for the disinfection of membranes in dialysis equipment, and as a preservative in hair shampoos.

Formaldehyde is often employed in the form of formaldehyde-releasing agents. Examples are (a) noxythiolin (hydroxymethylenethiourea), a bactericidal agent widely used both topically and in accessible body cavities, e.g. an irrigation solution in the treatment of peritonitis (Browne and Stoller 1970); (b) taurolin, in

which the amino acid taurine acts as a formaldehyde carrier (Browne et al. 1976, cf. Myers et al. 1980); (c) hexamine (methenamine), imidazole derivatives, triazines, and oxazolo-oxazoles. For further information, see Hugo and Russell (1999).

Glutaraldehyde

Glutaraldehyde (GTA) is a saturated five-carbon dialdehyde with an empirical formula of $C_5H_8O_2$ and a molecular weight of 100.12. It is highly active, reacting with enzymes and proteins but only slightly with nucleic acids; it prevents dissociation of free ribosomes. Probably because of increased interaction with $-NH_2$ groups, such activities increase with increasing pH, a factor of considerable importance to microbicidal activity (Russell 1994; Power 1997).

GTA possesses high microbicidal activity against bacteria and their spores, mycelial and spore forms of fungi, and various types of viruses, including human immunodeficiency virus (HIV) and enteroviruses (Hanson et al. 1994; Russell 1994). Despite earlier reports to the contrary, GTA is now considered to be mycobactericidal (Russell 1998a), although *Mycobacterium avium–intracellulare* might be of above-average resistance (Hanson 1988) and highly GTA-resistant strains of *Mycobacterium chelonae* have been isolated (van Klingeren and Pullen 1993; Walsh et al. 1999a, b, 2001; Fraud et al. 2001, 2003). In solution, GTA is more stable at acid than at alkaline pH, whereas the converse is true for its antimicrobial activity. In practice, 2 percent (or greater) solutions of GTA are alkalinated when required and are used within a stipulated period. Some formulations are available that appear to have overcome the problem of stability (Babb et al. 1980).

The dialdehyde is an important fixative in leather tanning, in electron microscopy and in biochemistry. It is employed widely for the disinfection or sterilization of medical equipment liable to damage by heat, in particular endoscopes. Nevertheless, there is the possibility of severe toxic reactions arising in personnel and its replacement by other equally microbiologically active agents is being actively pursued.

Ortho-phthalaldehyde

Ortho-phthaladehyde (OPA) (Alfa and Sitter 1994) is a recently inroduced (1998) cyclic dialdehyde. It is used, at a concentration of 0.55 percent and unadjusted pH, predominantly for the disinfection of endoscopes. OPA has potent lethal activity against gram-positive (including mycobacteria) and -negative bacteria (Alfa and Sitter 1994; Gregory et al. 1999; Walsh et al. 1999a, b, 2001; Fraud et al. 2001, 2003). At ambient temperatures, in-use concentrations and unadjusted pH, OPA has a low order of sporicidal activity (Walsh et al. 1999a, b), but sporicidal activity is observed when the concentration is increased and solutions made more alkaline.

Significantly, OPA is lethal towards GTA-resistant *M. chelonae* strains (Walsh et al. 1999a, b, 2001; Gregory et al. 1999; Fraud et al. 2001, 2003).

ALCOHOLS

Generally, alcohols rapidly kill bacteria (Morton 1983), including acid-fast bacilli, but are not sporicidal and have poor activity against some viruses, although HIV type 1 is susceptible to ethanol and isopropanol in the absence of organic matter (van Bueren et al. 1994). The presence of water is essential to the antimicrobial action of ethanol, which is most effective at concentrations of 60–70 percent (Price 1950).

Isopropanol (propan-2-ol) is a more effective bactericide. Benzyl alcohol (phenylmethanol) is a weak local anesthetic and also possesses antimicrobial properties. Phenylethanol (phenylethyl alcohol) is selectively active against gram-negative bacteria in mixed flora and is sometimes used as a preservative in ophthalmic solutions. Phenoxyethanol (phenoxetol) has significant activity against *P. aeruginosa* but less against other bacteria (Hugo and Russell 1999). Bronopol (2-bromo-2-nitropropane-1,3-diol) has a broad spectrum of activity, which is reduced in the presence of serum and especially of sulfydryl compounds. The effect of pH on its activity is complex (Croshaw and Holland 1984). Bronopol is widely used as a cosmetic preservative. Chlorbutanol (chlorbutol, trichloro-*t*-butanol) has been used as a bactericide in solutions for injection, but its instability presents a problem.

ISOTHIAZOLONES

Three isothiazolones have been studied comprehensively: 1,2-benzisothiazol-3-one (BIT), 5-chloro-*N*-methylisothiazol-3-one (CMIT), and *N*-methylisothiazol-3-one (MIT). They are widely used as industrial preservatives. Their activity is rapidly quenched by thiol-containing compounds and by valine and histidine, nonthiol amino acids (Collier et al. 1990).

DYES

Three groups of dyes find application as antimicrobial compounds:

- The acridines, which are heterocyclic compounds and which have been studied extensively. Albert (1979) showed that small changes in their chemical structure cause significant changes in biocidal properties, the most important factor being ionization, which must be cationic in nature. Acridines compete with H^+ ions for anionic sites on the bacterial cell and are more effective at alkaline than at acid pH.
- The triphenylmethane dyes (e.g. crystal violet, brilliant green, and malachite green), which have been used as topical antiseptics. However, their uses were

limited because they are effective only against gram-positive bacteria (Hugo and Russell 1999). This property does, however, have a practical application in the formulation of selective media for diagnostic purposes. Like the acridines, these dyes are more active at alkaline pH.

- The quinones, which are natural dyes imparting color to many forms of plant and animal life. Some members are important agricultural fungicides, notably chloranil and dichlone (Owens 1969; D'Arcy 1971).

HEAVY-METAL DERIVATIVES

The salts of heavy metals are sometimes employed as antimicrobial agents. The main antimicrobial use of copper derivatives is as algicides and fungicides; some copper compounds are used as preservatives in wood, cellulosics, paints, and fabrics (Hilditch 1999; Springle 1999).

Mercury compounds, in the form of organic derivatives (e.g. phenylmercuric nitrate and acetate), are still, despite criticism, sometimes used as preservatives for parenteral and ophthalmic solutions. Thiomersal serves this purpose for various immunological products. They are active against both gram-positive and gram-negative bacteria but are sporistatic, not sporicidal, at ambient temperatures (Russell 1998b; Hugo and Russell 1999).

Organotin compounds are used as biocides (e.g. fungicides, bactericides) and textile and wood preservatives (Hilditch 1999; McCarthy 1999).

Silver and its salts have long been used as antimicrobials. In recent years, silver nitrate has been employed to prevent infection of burns. Lowbury (1992) reviewed the use of this compound, at a concentration of 0.5 percent, for topical antimicrobial prophylaxis, and as a more satisfactory topical prophylactic, silver sulfadiazine (which, however, has the disadvantage that many bacteria are sulfonamide-resistant).

Russell and Hugo (1994) have described the antimicrobial properties and actions of various silver compounds.

PERMEABILIZING AGENTS

A permeabilizing agent is a chemical that increases the permeability of the outer membrane of gram-negative bacteria.

Chelating agents are not usually considered as being antimicrobial agents, but ethylenediamine tetraacetic acid (EDTA) enhances the activity of many antiseptics and disinfectants. The potentiating effects by EDTA on antibacterial agents acting against staphylococci (Kraniak and Shelef 1988) are likely to be the result of sequestration of metal ions present in the growth media rather than an increase in cellular permeability. In medicine, EDTA is used to treat chronic lead poisoning and pharmaceutically as a stabilizer in certain parenteral and ophthalmic preparations (Russell 1999a). In the context of disinfection, EDTA potentiates the effects of many antibacterial agents against gram-negative, but not usually gram-positive, bacteria (Russell and Furr 1977; Ayres et al. 1993, 1998a, b, c, d).

Polyethyleneimine (PEI) is a newer type of permeabilizer (Helander et al. 1997, 1998) that increases the permeability of gram-negative bacteria to several biocides.

ANILIDES

Anilides have the general structure C_6H_5NHCOR. In salicylanilide, R is C_6H_4OH and in carbanilide (diphenylurea) it is C_6H_5NH. Salicylanilide was introduced in 1930 as a fungistat for use in textiles and has also been used in ointment form for treating ringworm. Of the many substituted salicylanilides tested, the tribromo- and tetrachlorosalicylanilides have been the most widely used as antimicrobial agents. Their photosensitizing properties have, however, restricted their use in situations in which they come into contact with human skin. Trichlorocarbanilide, although one of the most potent members of the substituted carbanilides, has the same disadvantage.

QUINOLINE AND ISOQUINOLINE DERIVATIVES

There are three main groups: 8-hydroxyquinoline, 4-aminoquinaldinium, and isoquinoline derivatives. 8-Hydroxyquinoline (oxine) is a chelating agent active only in the presence of certain metal ions (Albert 1979). The 4-aminoquinaldinium derivatives are QACs that contain one or more quinoline ring systems; examples are laurolinium acetate and dequalinium chloride (a bis-QAC), both of which are active against gram-positive bacteria and many species of yeast and fungi (D'Arcy 1971). The most important isoquinoline derivative is hedaquinium chloride, another bisquaternary salt, which possesses antibacterial and antifungal properties.

PEROXYGENS

A peroxygen is a compound containing an –O–O– group. Hydrogen peroxide and peracetic acid are important peroxygens but others also find application.

Hydrogen peroxide

Hydrogen peroxide, H_2O_2, is active against gram-positive and gram-negative bacteria. Because they are unable to produce catalase, anaerobes are particularly susceptible. At high concentrations, hydrogen peroxide is sporicidal; this activity increases as the temperature is raised (Bloomfield 1999; Block 2001b). Activity is less affected by pH than many other biocides and is enhanced in the presence of cupric (Cu^{2+}) of ferric (Fe^{3+}) ions, which promote free-radical oxidation of organic compounds with peroxide. A mixture of peroxide and Cu^{2+}, but neither alone, produces strand

breaks in DNA (Sagripani and Kraemer 1989). It is environmentally friendly because its decomposition products are oxygen and water (Fraise 1999). Some uses are described in Table 1.

New hydrogen peroxide products have been described. A product based on accelerated and stabilized hydrogen peroxide (ASHP) had broad-spectrum activity, the undiluted form being sporicidal (>7/8 log reduction in 6 h), mycobactericidal (>6 log reduction in 20 min), and fungicidal (5 log reduction in 5 min) at 20°C (Sattar et al. 1999). AHSP was shown to be an excellent hard-surface cleaning agent with potent microbicidal activity (Rochon and Sullivan 1999; Alfa and Jackson 2001).

Peracetic acid

The best known example of a peracid is peracetic acid, CH_3COOOH, a strong oxidizing agent that is rapidly lethal for a wide range of microbes, including bacterial spores, viruses, and fungi (Baldry 1983; Broadley et al. 1995; Fraise 1999; Block 2001d). It has greater lipid solubility and more potent antimicrobial activity than hydrogen peroxide. It is sporicidal even at low temperatures and effective in the presence of organic matter (Block 2001c). The lethal species is the •OH radical (Clapp et al. 1994). Peracetic acid is frequently used as a chemosterilant (see section on New low-temperature sterilization technologies).

Performic acid

Performic acid, HCOOOH (see section on New low-temperature sterilization technologies) is a new proprietary liquid sterilant that is rapidly sporicidal (Rutala and Weber 2001a).

Ozone

Ozone, O_3, is an allotropic form of oxygen. Because of its powerful oxidizing properties (Schneider 1998; Weavers and Wickramanayake 2001), ozone is bactericidal, virucidal and sporicidal, although spores are some 10–15 times more resistant than vegetative cells. Gaseous ozone reacts with amino acids, especially those containing sulfur, and with RNA and DNA. In water, ozone is unstable chemically but activity persists because of the production of free radicals, including •OH. Its unstable nature means that ozone has to be produced on site (Schneider 1998).

SULFITES AND NITRITES

Traditional chemical food preservatives include common salt, sucrose, spices, and smoke and its components. Sulfur dioxide has for centuries been used as a fumigant and as a wine preservative. Metabisulfites have been widely used as antioxidants in foods (and in some pharmaceutical products), and sulfur dioxide and sulfites are used to preserve a variety of food products (Gould and Russell 1991; Sofos and Busta 1999).

Nitrite (NO_2^-) and nitrate (NO_3^-) have been used for centuries in meat processing. By reaction with heme proteins, nitrites are responsible for color formation in cured meat. They are antimicrobial, especially against outgrowing *Clostridium botulinum* spores. Nitrates function solely as a source of nitrite. The antimicrobial activity of nitrite is affected by many factors (Roberts et al. 1991). Carcinogenic nitrosamines are formed in some cured meat products cooked under certain conditions.

GASEOUS AND VAPOR-PHASE DISINFECTANTS

Gaseous and vapor-phase chemical agents have long been used to achieve disinfection and sterilization. Sulfur dioxide (obtained by burning sulfur) and chlorine found early application for fumigating sickrooms, but the scientific basis for their use was established only comparatively recently. A brief historical account is provided by Richards et al. (1984). Kaye and Phillips (1949) reviewed early studies on ethylene oxide (ETO).

The most important vapor-phase agents are ETO and formaldehyde.

Ethylene oxide

Ethylene oxide, $(CH_2)_2O$, is a colorless gas that is soluble in water, most organic solvents, and oils and diffuses into rubber in a manner similar to entering a solution (Joslyn 2001). It is inflammable when more than 3 percent is present in air, but this hazard can be overcome by mixing it with carbon dioxide or an appropriate hydrochlorofluorocarbon (HCFC) compound. Chlorofluorocarbons originally used for this purpose are no longer permitted (Alfa et al. 1998) and HCFCs are banned in some countries.

The antimicrobial activity of ETO depends upon several factors, notably relative humidity (RH), temperature, concentration, and time, and especially on the presence of water vapor (Ernst 1974; Joslyn 2001). Its high toxicity must be borne in mind when devising safe sterilization procedures. Furthermore, porous materials absorb the gas to various degrees during the sterilization cycle, so various periods of time after sterilization must be allowed for desorption of residual ETO. ETO is used as a decontaminating agent, for sterilizing ophthalmic and anesthetic equipment, crude drugs, and powders, and in veterinary practice for fumigating egg shells.

Formaldehyde

Formaldehyde gas can be generated by various means, namely evaporation of commercial formaldehyde solution (formalin), addition of formalin to potassium permanganate, or volatilization of paraformaldehyde,

$HO(CH_2)_nH$, where n = 8–100. Its antimicrobial activity depends upon several factors, including RH; it increases with RH up to a figure of 50 percent, but higher RH values confer little further advantage (Nordgren 1939). Formaldehyde is toxic, and inhalation of the vapor may pose a risk of carcinogenesis; adequate precautions should be taken to protect personnel. Low-temperature steam with formaldehyde (LTSF) has been used for disinfecting or sterilizing heat-sensitive materials (Russell 1999a). In the veterinary field, formaldehyde vapor is an important fumigant of animal buildings (Russell and Hugo 1987).

Other gases and vapors

These include

- β-Propiolactone (BPL). Its activity depends primarily on RH, concentration, and temperature. BPL may be carcinogenic, but it has been claimed to have a use in decontamination of animal premises. Liquid BPL is used widely in the preparation of many veterinary viral vaccines.
- Methyl bromide, CH_3Br. This is less active than ETO and is highly toxic but has been used as a fumigant.
- Propylene oxide, C_3H_6O. This is also less active than ETO. It has been used as a decontaminating agent, e.g. for animal feeds.
- Ozone. This is discussed above.
- Carbon dioxide, CO_2. This inhibits the growth of bacteria, including slime-producing bacteria, in soft drinks. Its activity depends upon low temperatures, its addition at an early stage, and its concentration.
- Hydrogen peroxide vapor. This has been used for the sterilization of surfaces in flexible and rigid-wall isolators and small rooms (Groschel 1995) and for endoscopes; it also has dental applications (Schneider 1998).
- Gaseous chlorine dioxide. This is unstable at high concentrations and must thus be generated on site (Schneider 1998).

Gas and vapor-phase plasmas are discussed in the section on New low-temperature sterilization technologies.

AERIAL DISINFECTANTS

An effective aerial disinfectant should be capable of being dispersed so as to ensure its complete and rapid mixing with infected air. An effective concentration should be maintained in the air and the disinfectant must be highly and rapidly active against air-borne microorganisms at different relative humidities. In addition, it should be nontoxic and nonirritant.

Early samples of aerial disinfectants were fumigants, such as sulfur dioxide and chlorine, employed in sickrooms. However, aerosols – which consist of a very fine dispersed liquid phase in a gaseous (air) disperse phase – are the most important form of aerial disinfectant.

Examples of aerial disinfectants are: (a) hexylresorcinol, which is vaporized from a thermostatically controlled hotplate; (b) lactic acid, which is effective but unfortunately an irritant at high concentrations; (c) propylene glycol, which may be used as a solvent for dissolving a solid disinfectant prior to atomization, but which is also a fairly effective and nonirritating antimicrobial agent in its own right; and (d) fumigants such as formaldehyde.

NATURAL ANTIMICROBIAL SYSTEMS

Natural antimicrobial systems (reviewed by Wilkins and Board (1989), Board (1995)) occur in animals, plants, and microorganisms. Major components of natural defense systems are classified broadly into inducible, e.g. complement, and constitutive. Principal representatives of the latter are enzymes, lysozyme (a cell-wall lytic agent, see section on Mechanisms of action of antimicrobial agents) and lactoperoxidase (LP), which mediates the production of compounds toxic to foreign, but not to host, cells. LP is most abundant in bovine cells. With a halide or thiocyanate and hydrogen peroxide, LP forms a potent antimicrobial lactoperoxidase system.

Additionally, transferrin in mammalian blood cells and milk, and lactoferrin in milk, may show antibacterial activity. They both act as iron-binding proteins, inducing lipopolysaccharide loss from the outer membranes of gram-negative bacteria and an increased cellular permeability (Russell and Chopra 1996).

Factors influencing activity

The activity of antimicrobial compounds may be influenced by various extraneous factors, including concentration, pH, time, temperature, type, number, growth phase, and location of microorganisms, and the presence of other agents that may reduce or increase their potency (Russell 1999a). A sound knowledge of these factors is essential for their most effective deployment, e.g. in the design of hospital disinfection policies (Coates and Hutchinson 1994) and in selecting disinfectant agents for particular purposes (Fraise 1999; Rutala and Weber 1999a, b).

CONCENTRATION OF ANTIMICROBIAL AGENT

The effect of concentration, or dilution, on the activity of an antimicrobial compound is not a simple arithmetic one. As was first pointed out by Krönig and Paul (1897), microbial death is not an all-or-nothing response but depends greatly on the period of contact and concentration (Figure 1).

In kinetic studies, the concentration exponent (dilution coefficient, η) is used to express the effect of

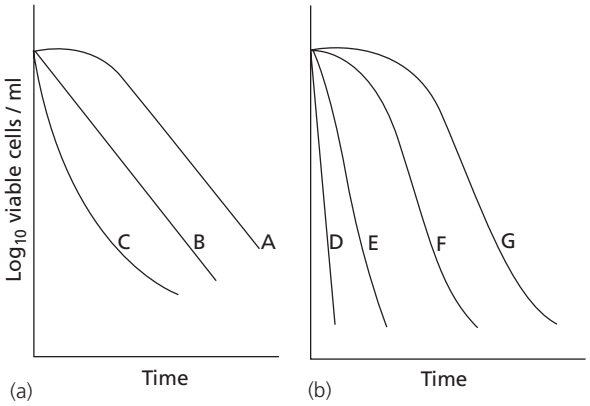

Figure 1 *Examples of time–survivor curves of bacterial suspensions exposed to disinfectants.* **(a)** *Bacterial responses: A, initial 'shoulder' followed by exponential death; B, exponential death; C, exponential death followed by 'tailing.'* **(b)** *Effects of different concentrations (D, highest; G, lowest) of phenol acting on* Escherichia coli. *At the lowest concentration, a sigmoidal curve is produced. This becomes less pronounced as the concentration increases, leading to an apparent straight-line response at the highest concentration.*

changes in concentration (or dilution) on cell-death rate. Its value may be determined by measuring the times necessary to kill the same number of bacteria in a suspension exposed to two concentrations of the antimicrobial agent. If C_1 and C_2 represent the two concentrations and t_1 and t_2 the respective times to reduce the viable population to the same end point, then

$$C_1 \eta t_1 = C_2 \eta t_2 \qquad (1)$$

from which

$$\eta = (\log t_2 - \log t_1)/(\log C_1 - \log C_2). \qquad (2)$$

Alternatively, η may be calculated from the slope of the straight line resulting when $\log_{10}$ death time ($\log t$) is plotted against $\log_{10}$ concentrations ($\log C$) (see Russell 1999a). Examples of η values are provided in Table 2.

A decrease in concentration of compounds with high η values results in a pronounced increase in the time necessary to achieve a comparable kill, other conditions remaining constant. By contrast, agents with low η values are much less affected (Table 2). Concentration is the single most important factor affecting biocidal activity (McDonnell and Russell 1999; Russell and McDonnell 2000).

Knowledge of the effect of concentration on antimicrobial potency is essential:

- in evaluating activity
- in testing medical and pharmaceutical products for sterility
- in ensuring adequate concentrations of preservative in pharmaceutical, cosmetic and food products, and
- in providing adequate concentrations of antiseptics and disinfectants for practical purposes (Russell 1999a).

TEMPERATURE

The activity of a disinfectant or preservative is usually increased when the temperature at which it acts is raised, although compounds vary considerably in response to temperature changes (Table 2).

A useful formula for measuring the effect of temperature on activity is given by

$$\theta^{T2-T1} = k_2/k_1 = t_1/t_2 \qquad (3)$$

in which θ is the temperature coefficient, k_2 and k_1 the rate (velocity) constants at temperatures T_2 and T_1, respectively, and t_2 and t_1 the respective times to bring about a complete kill at T_2 and T_1.

The velocity constant (k) can itself be obtained from a knowledge of the time (t) taken to reduce the initial viable number of cells (N_0) to a value N_t at time t, thus:

$$k = \frac{1}{t}\log_e \frac{N_o}{N_t} = \frac{1}{t} 2.303 \log_{10} \frac{N_o}{N_t}. \qquad (4)$$

The temperature coefficient, θ, refers to the effect on activity per 1°C rise and is nearly always between 1.0 and 1.5 (Bean 1967). It is more meaningful to specify the θ^{10} (also known as Q^{10}) value, which is the change in activity per 10°C rise in temperature (Table 2). At temperatures above about 40°C, there is little, if any,

Table 2 *Effects of concentration and temperature on activity of some antimicrobial agents*

Concentration exponents (η)[a]	Temperature coefficients (Q_{10} [or θ^{10}] values)[b]
Group A (η < 2)	θ^{10} 1.5–5
Hydrogen peroxide, mercurials, chlorhexidine, formaldehyde, QACs	Phenolics, ethylene oxide, β-propiolactone, phenols, cresols
Group B (η = 2–4)	θ^{10} 30–50
Parabens, sorbic acid	Aliphatic alcohols
Group C (η > 4)	
Aliphatic alcohols, phenolics, benzyl alcohol, phenethanol	

QAC, quaternary ammonium compound.
a) Based on Hugo and Denyer (1987).
b) Based on Bean (1967).

difference in activity between acid and alkaline glutaraldehyde, although the latter formulation is less stable (Gorman et al. 1980).

ENVIRONMENTAL PH

pH can influence the activity of antimicrobial agents in the following ways:

- Changes may occur in the molecule. Phenols and benzoic, sorbic, and dehydroacetic acids are effective predominantly in the unionized form and, as pH rises, their degree of dissociation increases. It is claimed that the dissociated form of sorbic acid may make a small contribution to activity.
- Changes may occur in the microbial cell surface. As pH increases, the number of negatively charged groups on the cell surface increases, causing enhanced binding of positively charged molecules, e.g. QACs (Hugo 1999b), dyes (Moats and Maddox 1978), acridines (Albert 1979), and chlorhexidine (Hugo 1999b). It must also be pointed out that the sporicidal activity of sodium hypochlorite is potentiated in the presence of methanol, although there is no simple relationship between activity, stability, and change of pH of the mixture (Coates and Death 1978). Maximal sporicidal activity and stability are achieved by buffering hypochlorite alone or a hypochlorite–methanol mixture to within a pH range of 7.6–8.1 (Death and Coates 1979).

INTERFERING SUBSTANCES

Organic matter

Organic soiling matter may be present as, for example, serum, blood, pus, soil, food residues, dried milk (milkstone), or fecal material; it can interfere with the action of an antimicrobial agent, usually because an interaction results in a reduced effective concentration of the latter (Russell 1999a).

Such reduction in activity is most noticeable with highly reactive compounds such as chlorine disinfectants. Iodine and iodophors, because of their lower chemical reactivity, are influenced to a rather lesser extent. Cationic agents such as QACs and chlorhexidine show a considerable reduction in activity, whereas the efficacy of phenols depends upon the actual phenolic compound; lysol, for example, retains much of its activity in the presence of feces and sputum (Russell 1999a).

Adequate precleaning before employment of a disinfectant, or a combination of disinfectant with a suitable detergent, may overcome the problem caused by the presence of organic soil. However, it should be noted that the activity of disinfectants may suffer considerably in the presence of certain detergents.

Surface-active agents

Cationic bactericides and anionic surfactants are incompatible. Low concentrations of nonionic surfactants such as polysorbates, tritons, and tergitols increase the activity of cationic agents and of parabens (Allwood 1973), whereas at higher concentrations of the nonionic detergents, significantly greater concentrations of the antimicrobial substances are necessary to inhibit or kill microbes. It is believed that below the critical micelle concentration (CMC) of the nonionic compound, potentiation occurs by action on the surface layers of the bacterial cell, resulting in enhanced permeability to the antimicrobial agent. Above the CMC, it either forms a complex with the antimicrobial compound or the latter is partitioned between the aqueous and micellar phases, only the concentration in the aqueous phase being available for microbial attack.

Because of their ability to inactivate various types of antimicrobial compounds, nonionic surfactants are frequently employed as neutralizing agents in sterility testing and in antimicrobial evaluation (Russell et al. 1979; Sutton 1996; Fassihi 2001).

Oils

A problem encountered in the formulation of pharmaceutical and cosmetic creams and emulsions is that the antimicrobial activity of a preservative may be high in aqueous conditions but much less so when an oil is present. The reason for this is that the preservative is partitioned between the oily and aqueous phases (Bean 1972; Fassihi 2001).

Other factors

The hardness of the water with which disinfectants are prepared or diluted is a contributory factor in reducing the effectiveness of QACs and iodophors; black (but not white) fluids are incompatible with hard waters. Partitioning into rubber may cause problems in the preservation of multiple dose parenteral and ophthalmic solutions. Relative humidity has a profound influence on the activity of gaseous disinfectants (see section on Gaseous and vapor-phase disinfectants).

CONDITION, GROWTH PHASE, AND SIZE OF MICROBIAL POPULATION

It is clearly easier for an antimicrobial agent to be effective when there are few microorganisms against which to act. Adequate and thorough precleaning is usually an important prerequisite to a disinfection process. Exponential phase cells of *S. aureus* (Luppens et al. 2002) and *Listeria monocytogenes* (Luppens et al. 2001) are more susceptible to cationic and oxidizing biocides than cells in the decline phase.

The association of bacteria (or other microorganisms) with solid surfaces leads to the production of a biofilm, a consortium of bacteria organized within an extensive exopolymer (glycocalyx). Within the depths of the biofilm, growth rates are likely to be reduced as a

consequence of nutrient limitation (Poxton 1993), which can alter the bacterial cell surface and hence be responsible for modified sensitivity to antibacterial agents (Costerton et al. 1987; Carpentier and Cerf 1993; Stickler and King 1999). This is one reason for the reduced sensitivity of the sessile cells found in biofilms; other reasons include chemical reaction with glycocalyx and prevention by the glycocalyx of access of biocide to the underlying cells. This aspect is considered in more detail below (see Biofilms and resistance).

Types of microorganism

The activity of antimicrobial agents depends greatly upon the type of microorganism present. It is therefore pertinent to examine the sensitivity of various types of microbes which, for convenience, have been classified into the following groups.

GRAM-POSITIVE BACTERIA (COCCI)

Generally, cocci are more sensitive to antimicrobial agents than are gram-negative bacteria (Baird-Parker and Holbrook 1971; Russell and Gould 1988). Cocci are readily killed by halogens, phenols, especially bisphenols, and QACs. However, multiple antibiotic-resistant *S. aureus* and *S. epidermidis* may show reduced sensitivity to cationic-type agents (see Types and uses of chemical agents). Clinical isolates of enterococci (*Enterococcus faecium* and *E. faecalis*) are often antibiotic-resistant and include vancomycin-resistant enterococci (VRE), but do not appear to be more resistant to chlorhexidine than staphylococci (Baillie et al. 1992; Alqurashi et al. 1996). The effects of biocides on antibiotic-resistant cocci are discussed by Day and Russell (1999).

MYCOBACTERIA

The sensitivity of acid-fast bacteria to disinfectants is intermediate between that of other nonsporulating bacteria and bacterial spores (Ayliffe et al. 1993; Favero and Bond 1993; Russell 1998a; Lauzardo and Rubin 2001). QACs and dyes inhibit tubercle bacilli but do not kill them. *Mycobacterium tuberculosis* is also insensitive to chlorhexidine, acids, and alkalis, but moderately sensitive to amphotericsurface-active agents, including the Tego compounds. Of the phenols, 2-phenylphenol is particularly effective, but the bisphenols are inactive. Alcohols, liquid and vapor-phase formaldehyde, formaldehyde–alcohol, iodine–alcohol, and ethylene oxide are all tuberculocidal; despite earlier doubts to the contrary, so is GTA (Favero and Bond 1993). However, *M. avium–intracellulare* (Hanson 1988) and *M. chelonae* (van Klingeren and Pullen 1993) may be resistant to the dialdehyde (see also Terminology).

GRAM-NEGATIVE BACTERIA

Many types of gram-negative bacteria, especially *Escherichia coli*, *Klebsiella* spp., *Proteus* spp., *P. aeruginosa*, and *Serratia marcescens*, are increasingly implicated as hospital pathogens. In the veterinary context, bacteria causing zoonotic diseases include *Campylobacter* spp., salmonellae, and brucellae (Linton 1983; Russell et al. 1984). Gram-negative bacteria are usually less sensitive than gram-positive bacteria, and *P. aeruginosa* and *Proteus* spp. may contaminate solutions of QACs (Russell et al. 1986). These bacteria, and others such as *Providencia stuartii*, are also more resistant to chlorhexidine than is *E. coli* (Ismaeel et al. 1986).

Legionella pneumophila is frequently found in domestic water and cooling-water systems of large buildings. Although outbreaks of legionnaires' disease are uncommon, they are associated with high morbidity and some deaths when they occur. Adequate control measures must be taken. Neither raising the temperature of hot-water systems nor continuous chlorination alone is completely effective. Control of the organism in recirculating water systems has also been studied, but extrapolation from laboratory conditions to such systems is often unrealistic because of possible interaction between the biocide and other water-treatment chemicals as well as slime (Elsmore 1999). Wang et al. (1979) found hypochlorite to be effective against *L. pneumophila*, but Kurtz et al. (1982) showed a chlorinated phenol to be more effective than a QAC–tributyl tin oxide mixture or sodium dichloroisocyanurate. Bronopol is effective both under laboratory conditions and in cooling towers (Elsmore 1999).

BACTERIAL SPORES

Many antibacterial compounds have no or little sporicidal activity. Nevertheless, such chemicals are not entirely without effect on spores because they may prevent germination or outgrowth, or both. Chemicals that are sporistatic rather than sporicidal include phenols and cresols, parabens, QACs, biguanides, alcohols, dyes, and mercury compounds. Comparatively few substances are sporicidal and even then the process may be comparatively slow. Examples of sporicides are hydrogen peroxide, hypochlorites, glutaraldehyde, formaldehyde, iodine compounds, ethylene oxide, peracetic acid, and β-propiolactone (Russell 1990a, 1998a, b; Bloomfield and Arthur 1994; Setlow 1994; Bloomfield 1999). Vegetative, rod-shaped cells of *Bacillus* spp. are considerably more sensitive to biocides than the corresponding spore forms (Russell 2003b, c).

MOLDS AND YEASTS

Several species of molds and yeasts are pathogenic. Others are important in spoiling foods and pharmaceutical and cosmetic products.

Many compounds show both antibacterial and antifungal activity, although the latter may be fungistatic rather than fungicidal (Russell and Furr 1996; Russell 1999c). These include phenolics (notably the halogenated members and hexachlorophane), QACs, oxine (8-hydroxyquinoline), diamidines, organic mercury derivatives, and the parabens. Sorbic acid shows significant antifungal activity at low pH values when it occurs in solution mainly in the undissociated form. At higher pH values, activity is lost. Fungal spores are often resistant to chemical disinfectants (Russell 1999c).

PROTOZOA

Several distinctly different types of protozoa, including *Giardia*, *Cryptosporidium*, *Naegleria*, *Entamoeba*, and *Acanthamoeba*, are potentially pathogenic and may be acquired from water. Furthermore, their life cycles may contain a resistant cyst stage (Jarroll 1999). Agents, in ascending order of efficacy, that are cysticidal towards *Giardia muris* cysts are monochloramine, free chlorine, iodine, chlorine dioxide, and ozone (Jarroll 1988, 1999). Chlorine dioxide is more effective against *Cryptosporidium* oocysts than is either free chlorine or monochloramine; these cysts are also sensitive to ozone (Korich et al. 1990).

Acanthamoeba spp. may cause corneal keratitis, sometimes associated with the use of contaminated contact lenses or contact-lens solutions. Whereas trophozoites are readily inactivated by contact-lens disinfecting solutions, cysts are more refractory (Khunkitti et al. 1997, 1998a, b, 1999; Turner et al. 1999, 2000a, b) and the presence of proteinaceous matter is an additional hazard (Seal and Hay 1992).

VIRUSES

Several bactericidal agents are virucidal, but antibacterial activity does not necessarily imply antiviral potency. An excellent comprehensive treatise of virus disinfection is that presented by Grossgebauer (1970). Viruses are classified primarily as to whether they contain DNA or RNA, but the presence or absence of a lipid envelope is in general more important in relation to disinfection. An important hypothesis was put forward in 1963 and modified some 20 years later by Klein and Deforest (1983) (see also Prince and Prince 2001), who classified viruses into three groups:

1. lipid-enveloped viruses, e.g. herpes simplex virus (HSV), HIV, hepatitis B virus (HBV)
2. small nonenveloped viruses, e.g. picornaviruses, parvoviruses
3. larger nonenveloped viruses, e.g. rotaviruses.

The order of these groups, in terms of biocide sensitivity, is $1 > 3 > 2$.

Detailed knowledge of the inactivation of viruses has, in the past, been important in the preparation of vaccines such as inactivated (Salk) poliomyelitis vaccine, in which formaldehyde was used as the virucidal agent. Nowadays, with the current importance of HIV, HBV, and hepatitis A virus (HAV), plus the need to prevent the transmission of viral infection, it is essential to have a sound knowledge of viral inactivation. Important virucidal agents include CRAs, formaldehyde (in inactivated vaccine production), glutaraldehyde at alkaline pH, and peracetic acid (Springthorpe and Sattar 1990; Sattar et al. 1994, 2001; Maillard and Russell 1997; Maillard 2001; Prince and Prince 2001). Bacteriophages have been considered as indicator 'organisms' for assessing the virucidal activity of biocides (Davies et al. 1993; Maillard et al. 1995; Maillard and Russell 1997) (see also Evaluation of antimicrobial activity).

Viruses also cause many diseases of animals. Lists of approved dilutions of approved disinfectants for veterinary use in the UK are frequently published by the Department for Environment, Food and Rural Affairs (DEFRA) (formerly the Ministry of Agriculture, Fisheries and Foods). These are for general use and in connection with certain Statutory Orders applying to viral infections (foot-and-mouth disease, swine vesicular disease) and bacterial disease (tuberculosis). Porcine parvovirus, which causes reproductive failure in swine, is quite resistant to disinfectants, only sodium hypochlorite and sodium hydroxide being rapidly virucidal; by contrast, two enveloped swine viruses (pseudorabies and transmissible gastroenteritis viruses) are highly sensitive to a wide range of disinfectants (Quinn and Markey 1999).

Russell (1990b) has provided a comprehensive list of the susceptibility of different types of viruses to heat and chemical biocides, as well as considering acid stability and sensitivity to the organic solvent ether, which inactivates most lipid-enveloped viruses.

PRIONS

Prions are responsible for a distinct group of unusual neurological diseases, the transmissible degenerative encephalopathies (TDE) or transmissible spongiform encephalopathies (TSE), and are sometimes referred to as unconventional transmissible agents. Examples of TDEs are Creutzfeldt–Jakob disease (CJD) and new variant Creutzfeldt–Jakob disease (nvCJD), scrapie in sheep, bovine spongiform encephalitis (BSE), and kuru.

Prions are composed of an altered protein and are inordinately resistant to most chemical and physical agents, including glutaraldehyde, formaldehyde, organic solvents, chlorine dioxide, iodine, strong acids, normal autoclaving conditions, dry heat, and ionizing and ultraviolet radiations (Taylor 1999; Baron et al. 2001). However, as prions have yet to be purified (Taylor 2004), it is difficult to state whether this is an intrinsic property or to what extent it is influenced by the protective effect of host tissue. They are inactivated by strong

alkali, guanidinium hydrochloride (or isocyanate), and sodium hypochlorite (Baron et al. 2001).

Evaluation of antimicrobial activity

A detailed survey of the numerous published methods for evaluating antimicrobial activity is outside the scope of this chapter. A summary is provided in Table 3 and the following should be consulted for additional information: Quinn (1987), CEN (1996), Quinn and Carter (1999), Reybrouck (1999), and Cremieux et al. (2001).

The evaluation of virucidal activity is not an easy matter (Bellamy 1995). Viruses are unable to grow in artificial laboratory culture media. Another appropriate system, usually involving living cells, must thus be employed. In essence, the principles of testing follow methods of evaluating bactericidal or fungicidal activity in that the virus is exposed to appropriate concentrations of disinfectant in suspension, or on a carrier, e.g. glass coverslips, as used with herpes virus and poliovirus (Tyler and Ayliffe 1987). Inactivation is then tested in an appropriate manner, care being taken to ensure that residual disinfectant is neutralized and that the antimicrobial agent has no toxic effects on host cells.

Estimation of virucidal activity can be made using the following systems (see also Quinn and Carter 1999; Sattar and Springthorpe 2001):

- *Tissue culture* or fertile eggs, which after incubation are examined for signs of viral infection.
- *Plaque-counting* procedures, which have been used for various viruses, e.g. herpes and poliovirus (Tyler and Ayliffe 1987) and human rotaviruses (Lloyd-Evans et al. 1986; Springthorpe et al. 1986).
- Use of an *'acceptable' animal model*, e.g. the chimpanzee, for studying survival of HBV. The discovery of hepadnaviruses that infect ducks and small animals might provide a suitable alternative (Tsiquaye and Barnard 1993).
- *Immunological reactions*: tests for the inactivation of the hepatitis B surface antigen (HBsAg) were at one time used to assess the efficacy of disinfection procedures for this virus. However, since this component is much more stable to chemical and physical agents than those viral parts conferring infectivity, the method is no longer used.
- *Endogenous reverse transcriptase*: HIV is an enveloped RNA retrovirus. After HIV enters a cell, RNA is converted to DNA under the influence of an enzyme, reverse transcriptase. HIV replicates in certain T lymphocytes and in the assay reverse transcriptase activity is not a satisfactory alternative to tests in which infectious HIV can be detected in systems employing fresh human peripheral blood mononuclear cells (Resnick et al. 1986).

Table 3 *Examples of methods used for evaluating antimicrobial activity*

Test/evaluation	Examples of methods available[a,b]	Comments
Bacteriostatic/fungistatic potency (MIC determination)	Broth/agar serial dilution methods; agar diffusion methods	Provide preliminary information only
Bactericidal/fungicidal activity	(1) Suspension tests with determination of numbers of survivors. Include sporicidal and mycobactericidal estimations (AFNOR 1989)	(1) Neutralization of agent essential to prevent 'carry-over' into recovery medium;[a] rapid methods increasingly being studied
	(2) European Suspension Test	(2) 5 Log_{10} reduction in specified period
Phenol coefficient tests	RW, CM, AOAC methods	Compare activity of a test phenolic vs. a standard (phenol)[a]
Capacity-type tests	Kelsey–Sykes test	Refers to capacity of a disinfectant to retain its activity when repeatedly challenged by test organisms
Carrier tests	AOAC use-dilution confirmatory test; DGHM test	Organisms are dried on to appropriate carriers
Virucidal tests	Tissue culture, eggs, plaque counting; animal models; enzyme activity	See text
Skin disinfection	MIC and lethal effects (presence of serum or blood); skin test at 37°C	
Aerial disinfection	Closed-chamber evaluation of microbial population before and after exposure to aerial disinfectant	
Preservative activity	MIC evaluation, lethal activity; challenge testing of preserved pharmaceutical and cosmetic products	See British Pharmacopoeia (2000)

AFNOR (1989), Association Française de Normalisation; AOAC (1990), Association of Official Analytical Chemists; CM, Chick–Martin; DGHM, Deutsche Gesellschaft für Hygiene und Mikrobiologie; MIC, minimum inhibitory concentration; RW, Rideal–Walker.

a) See also text.

b) Suitable tests must be done where relevant to demonstrate adequate neutralization of antimicrobial agents.

- *Use of bacteriophages* as model systems: bacteriophages have been suggested as model systems for human viruses (Davies et al. 1993). Certainly, they have several advantages such as ease of handling and fairly rapid and reproducible results (Maillard et al. 1995). Their resistance to biocides should, of course, mimic a particular virus (or viruses), e.g. coliphage MS2 has the same order of response to some biocides as poliovirus.

Mechanisms of action of antimicrobial agents

Considerable progress has been made in understanding the mechanisms of action of many antibacterial agents (Denyer and Stewart 1998; Denyer 2002, Russell 1998a, b, 2002b, 2003b; Hugo 1999b). The same is not always true when the target organisms are yeasts, fungi, bacterial spores or viruses (Russell et al. 1997; Russell 2003b).

The initial reaction between an antimicrobial agent and a microbial cell takes place at the cell surface. This is followed by penetration of the chemical to reach its site(s) of action, usually within the cell itself, while some act by 'physical' puncture of cell walls. Unlike most antibiotics, however, many biocides have more than one site of action and it is thus often difficult to elucidate the exact mechanism whereby cellular inactivation is achieved. Furthermore, secondary effects may make a significant contribution to the overall process. Conversely, McMurray et al. (1998a) found that the phenylether, triclosan, acts on a specific bacterial target, inhibiting lipid synthesis in *E. coli*.

ACTION ON NONSPORULATING BACTERIA

Uptake of an antibacterial agent by bacteria represents an early manifestation of its effect, although there is little information available about uptake by mycobacteria (Russell 1996, 2003b).

Different agents have different sites and modes of action. Data are presented below, and summarized in Table 4, of the ways in which they act (Russell and Russell 1995; Russell and Chopra 1996). It must again be emphasized, however, that little is known about the mechanisms of inhibition and inactivation of mycobacteria (Russell 1996).

Cell-wall or cell-envelope effects

EDTA is not a powerful bactericide in its own right. Generally, it has little effect on gram-positive bacteria or fungi but is active against certain gram-negative bacteria, especially *P. aeruginosa* (Hugo and Russell 1999). Its usefulness resides in the fact that it is a chelating agent that combines with cations associated with the outer membrane (OM) of gram-negative bacteria with the release of some 30–50 percent of OM lipopolysaccharide (LPS). These changes in the OM render the cells more sensitive to many chemically unrelated compounds such as lysozyme, QACs, dyes, and phenols (Hugo 1999b).

EDTA thus increases the permeability of gram-negative bacteria. Other chemicals that act in a similar manner include sodium hexametaphosphate, gluconic acid, citric acid, and malic acid (Vaara 1992; Ayres et al. 1993, 1998a, b) and PEI displaces Mg^{2+}, thereby opening up the OM of gram-negative bacteria (Helander et al. 1997, 1998).

GTA has several effects on nonsporulating bacteria (Russell 1994). It causes cross-linking of the peptidoglycan in gram-positive bacteria so that lysis of this component is reduced on subsequent treatment with lysozyme (*Bacillus subtilis*) or lysostaphin (*S. aureus*). GTA interacts with protein in the cell envelope of gram-negative bacteria, with consequent reduction of lysis by sodium lauryl sulfate or EDTA–lysozyme.

The dialdehyde increases resistance to lysis of protoplasts and spheroplasts, by stabilizing the cytoplasmic membrane. OPA is much less efficacious as a cross-linking agent (Walsh et al. 1999a, b, 2001).

Membrane-active agents

Various chemical agents effect perturbation of homoeostatic mechanisms in bacteria in one of two ways (Gould 1988; Russell and Hugo 1988). In the first, leakage of intracellular materials is promoted by their physical interaction with the cytoplasmic membrane. In the second, there is a specific attack on the insulatory function of the membrane, such that the proton-motive force (pmf) across it is either discharged or prevented from forming.

Leakage can be considered as being a measure of the generalized loss of function of the cytoplasmic membrane as a permeability barrier, the rate and extent of leakage usually depending on the concentration of the inhibitor and the time and temperature of exposure. Leakage may be related to bacteriostasis but not necessarily to cell death (Denyer and Stewart 1998). Examples of antibacterial agents that induce leakage are cationic, anionic, and polypeptide surface-active agents, phenol, chlorhexidine, parabens, hexachlorophane (hexachlorophene), phenoxyethanol salicylanilides, and triclosan. These effects are not, however, necessarily responsible for cell death. Triclosan, for example, has been shown to have a specific effect on enoyl-ACP reductase (FabI) in *E. coli* (McMurry et al. 1998a, b). Heath et al. (2001) proposed that this is the only target for triclosan in this organism, and that the phenylether does not possess membrane-disruptive properties (cf. McMurry et al. 1998a). FabK and FabL are the respective enoyl-ACP reductase isoforms from *Streptococcus pneumoniae* and *B. subtilis*. FabK is triclosan-resistant

Table 4 *Mechanisms of antibacterial action*[a]

Target site	Example(s)[b]	Mechanism(s)
Outer cell layers (cell wall/ outer membrane)	GTA, OPA	Interaction with $-NH_2$ groups, e.g. proteins, peptidoglycan (OPA less effective than GTA)
	EDTA	Chelation of divalent cations, especially Mg^{2+}
	PEI	Displaces Mg^{2+}
	Lysozyme	β,1–4 links in peptidoglycan
	Cationic biocides	
	CHA, QACs, DBPI, PHMB	Outer-membrane damage, thereby promoting own entry postulated
Cytoplasmic (inner) membrane	Phenols	Generalized membrane damage
	Triclosan	Membrane damage, but at low concentrations inhibits enoyl reductase
	QACs	Generalized membrane damage
	CHA	Low concentrations affect membrane integrity, high concentrations inhibit congeal protoplasm
	Alexidine, PHMB	Phase separation and domain formation of acidic phospholipids
	Hexachlorophane	Inhibits membrane-bound electron-transport chain
	Phenoxyethanol	Proton-conducting uncoupler
	Sorbic acid	Transport inhibitor (effect on pmf); another unidentified mechanism?
	Parabens	Low concentrations inhibit transport, high concentrations affect membrane integrity
	Metallic compounds[c]	
	mercury, silver, copper	Interaction with –SH groups in proteins and enzymes
	Isothiazolones[c]	Interaction with –SH groups in proteins and enzymes
	Bronopol[c]	Oxidizes thiol groups to disulfides
Cytoplasmic constituents	*Alkylating agents*	
	ETO, BPL, PO, formaldehyde	Combination with amino, carboxyl, sulfydryl, and hydroxyl groups in protein; ETO also interactions at N-7 guanine moieties in DNA
	Cross-linking agents	
	GTA, OPA, formaldehyde	Intermolecular protein cross-links; OPA less effective but enters mycobacteria more readily than GTA
	Intercalating agents, e.g. acridines	Acridines intercalate between two layers of base pairs in DNA
	Phenethyl alcohol	Inhibits DNA synthesis
	Oxidizing agents	
	1 Hypochlorites[c]	Progressively oxidize thiol groups to disulfides, sulfoxides, or disulfoxides
	2 Hydrogen peroxide[c]	Formation of free hydroxyl radicals (•OH) causes oxidation of thiol groups in enzymes and proteins
	3 Peracetic acid[c]	Possibly disrupts thiol groups in proteins and enzymes
	Iodine	Interaction with cytoplasmic protein

BPL, β-propiolactone; CHA, chlorhexidine diacetate; DBPI, dibromopropamidine isethionate; EDTA, ethylenediamine tetraacetate; ETO, ethylene oxide; GTA, glutaraldehyde; OPA, *ortho*-phthalaldehyde; PEI, polyethyleneimine; PHMB, polyhexamethylene biguanide; pmf, proton-motive force; PO, propylene oxide; QACs, quaternary ammonium compounds.

a) For further information, see Russell and Chopra (1996).

b) Some agents affect more than one target site.

c) These compounds might affect enzymes and proteins in both the cytoplasmic (inner) membrane and the cytoplasm.

whereas FabL is reversibly inhibited by triclosan. The expression of either FabK or FabL in *E. coli* produces cells with increased triclosan resistance of three orders of magnitude. In *S. aureus*, only FabI is expressed and overexpression results in an increased MIC of triclosan (Slater-Radosti et al. 2001). Suller and Russell (1999, 2000) found that triclosan caused leakage from *S. aureus*. Triclosan and isoniazid inhibit InhA (an FabI analogue) in *M. smegmatis* and *M. tuberculosis*, but unlike isoniazid, triclosan may have a second target in *M. smegmatis* (Heath et al. 2001). Two aspects of triclosan action are important, namely its growth-inhibitory and lethal effects. It is unlikely that inhibition of enoyl reductase is solely responsible for its lethal effect

and membrane damage, including leakage, must play an important role at higher triclosan concentrations.

Chlorhexidine has a biphasic effect on membrane permeability in which an initial high rate of leakage occurs as the biguanide concentration increases, with a progressive decrease in leakage at higher chlorhexidine concentrations as a consequence of coagulation or precipitation of the cytosol (Hugo 1999b).

Both alexidine and the polymeric biguanide PHMB produce lipid phase separation and domain formation of the acidic phospholipids in the cytoplasmic membrane (Broxton et al. 1984, Chawner and Gilbert 1989a, b; Gilbert et al. 1990a, b). Chlorhexidine and QACs also combine with membrane phospholipids but do not bring about lipid phase separation and domain formation.

Ethanol and isopropanol are membrane disrupters, inducing a rapid leakage of intracellular constituents; disorganization of the membrane probably results from their penetration into the hydrocarbon core of the membrane (Seiler and Russell 1991).

Mitchell's (1961) chemiosmotic theory seeks to explain active transport, synthesis of adenosine triphosphate (ATP) and flagellar movement. During metabolism, protons are extruded to the exterior of the bacterial cell, resulting in acidification of the exterior and positivity in charge relative to the cell interior. It may be expressed mathematically as

$$\Delta p = \Delta\psi - Z\Delta pH \qquad (5)$$

in which Δp is the pmf, ψ the membrane electric potential, ΔpH the transmembrane pH gradient, and Z a constant (2.303 RT/F) with a value of 61 at 37°C that is used to convert pH values to millivolts.

Several chemicals that are antiseptics, disinfectants, or preservatives behave in a manner similar to 2,4-dinitrophenol (DNP), i.e. they act as uncouplers of oxidative phosphorylation. Examples include 2-phenoxyethanol, bisphenols, and pentachlorophenol. Tetrachlorosalicylanilide discharges the membrane potential, $\delta\psi$, in *E. faecalis*. The thiobisphenol, fentichlor, behaves very much like DNP, having a direct action on the collapse of a proton potential (Bloomfield 1974). Phenoxyethanol and the alkyl phenols act as proton-conducting uncoupling agents. Pharmaceutical and food preservatives such as the parabens and lipophilic acids (propionic, sorbic, 4-hydroxybenzoic) inhibit the active uptake of some amino and oxo acids in *E. coli* and *B. subtilis*. Sorbic acid affects the pmf in *E. coli* and accelerates the movement of H^+ ions from low pH media into the cytoplasm. Sorbic acid appears to dissipate ΔpH, having a much smaller effect on $\Delta\psi$ (Eklund 1983, 1985a, b; Salmond et al. 1984).

Agents acting on nucleic acids and proteins

Intercalation: The antimicrobial activity of the acridines increases with degree of ionization (Albert 1979). Ionization is the most important factor governing their activity, but it must be cationic in nature, because acridine derivatives that are ionized to form anions or zwitterions are only poorly antibacterial by comparison. The acridines induce filamentous forms in gram-negative bacteria, inhibit DNA synthesis, and combine strongly with DNA, although binding to other sites such as RNA, cell envelopes, and ribosomes has also been reported. Binding to DNA has been studied extensively. The classic studies of Lerman (1961) suggested that the planar drug molecules become intercalated between adjacent base pairs in DNA. Binding to DNA occurs by two distinct mechanisms (Peacocke and Skerrett 1956). In the first, there is a first-order reaction with one proflavine molecule binding to every four or five nucleotides, whereas in the second, there is a slower higher order of reaction with one molecule per single nucleotide.

Alkylation: Alkylation is defined as the conversion of H-X→R-X, where R is an alkyl group. Biological activity of alkylating agents is indicated by reaction with nucleophilic groups.

Epoxides, of which ethylene oxide is an example, interact with amino acids and proteins. Ethylene oxide causes hydroxyethylation of amino acids and combines with the amino, carboxyl, sulfydryl, and hydroxyl groups of proteins (Russell 1976). Alkylation of phosphated guanine in nonsporing bacteria has been proposed as the primary reason for the lethal effect of ethylene oxide (Michael and Stumbo 1970; Russell 1976).

It has been suggested that formaldehyde also acts by its alkylating effect. Binding to RNA is reversible up to a point (Staehelin 1958). Interaction of formaldeyde with T2 bacteriophage DNA and with protein has been described (Grossman et al. 1961).

The reaction of GTA with nucleic acids follows pseudo-first-order kinetics at high temperatures but there is little evidence for the formation of intermolecular cross-links. GTA inhibits synthesis of protein, DNA and RNA in *E. coli*, but this is believed to arise from an inhibition of precursor uptake as a consequence of protein–dialdehyde interaction in the outer structures of the cell.

Interaction with enzymes: Metals such as mercury and silver interact with thiol (–SH) groups on enzymes to form mercaptides (Hugo 1999b). This reaction may be reversed by excess of an –SH compound such as sodiumthioglycollate or cysteine, an important finding since such agents are used to inactivate metals in microbicidal testing (Russell et al. 1979; Russell and Hugo 1994). Bronopol also interacts with –SH groups (Hugo 1999b).

Other effects: Silver salts produce structural changes in the cell envelope of *P. aeruginosa* and the Ag^+ ion reacts preferentially with the bases rather than the phosphate groups in DNA (Russell and Hugo 1994).

ACTION ON BACTERIAL SPORES

Bacterial spores are not inactivated rapidly or readily at ambient temperatures (Bloomfield and Arthur 1994;

Bloomfield 1999) and comparatively few chemicals are sporicidal (Russell 1990a, b, 1998b). The mechanism of action of those that are sporicidal is often poorly understood, although progress continues to be made.

Although it is possible to correlate changes in cell structure with the development of resistance (sporulation) or sensitivity (germination and outgrowth), it is rather more difficult to identify the mechanism whereby death is brought about (Knott et al. 1995). Superoxidized water does not cause DNA damage and dipicolinic acid (DPA) is not released; it is considered that *B. subtilis* spores are inactivated by a modification of the inner membrane, which becomes nonfunctional in germinated spores (Loshon et al. 2001). Hydrogen peroxide-treated spores maintain their permeability barrier, there being no DPA release even after subsequent heat treatment. It is unlikely that significant damage occurs to the spore inner membrane (Melly et al. 2002), although Shin et al. (1994) found that peroxide sensitizes spores to heat damage. Usual targets for peroxide attack on membranes are polyunsaturated acids, which are present in extremely low levels in spores (Melly et al. 2002). Prolonged exposure of spores to 15 percent peroxide at elevated but sublethal temperatures, or to high peroxide concentrations, causes spore lysis with major damage to coat, cortex and protoplast (Shin et al. 1994). Imlay and Linn (1988) are of the opinion that one mechanism of hydrogen peroxide action is the generation of •OH radicals that cleave the DNA backbone. Peracetic acid was found by Clapp et al. (1994) to be the most potent peroxygen in their test series, the lethal moiety being •OH radicals. Reduced transition-metal ions sensitize spores to peracetic acid (Marquis et al. 1995).

Low concentrations (0.01 percent) of alkaline GTA inhibit germination and outgrowth, whereas much higher concentrations must be used for long periods to kill spores (Russell 1990a, 1999c). In fact, as with formaldehyde (Spicher and Peters 1981), it has been shown (Power et al. 1988; Williams and Russell 1993) that it is possible to revive a very small proportion of GTA-treated spores by means of a sublethal heat shock or by sodium hydroxide or other treatment. It is thus possible that the dialdehyde is a less effective sporicide than orginally thought, but that its cross-linking effect on bacterial spores will, under ordinary circumstances, be sufficient to prevent spore germination and subsequent vegetative development. Cabrera-Martinez et al. (2002) provided evidence that GTA does not damage spore DNA but eliminates the spore's ability to germinate and that OPA-treated spores that cannot germinate are not recovered by artificial germinants or by treatment with sodium hydroxide or lysozyme.

The enzyme, lysozyme, hydrolyzes β,1–4-linkages between *N*-acetylmuramic acid and *N*-acetylglucosamine in the spore peptidoglycan in coatless spores. Sodium nitrite breaks the peptidoglycan chain at the muramic lactam residues unique to spores. Hypochlorites interact strongly with spore coats, but their major site of sporicidal action is believed to be on the cortex (Bloomfield and Arthur 1994; Bloomfield 1999). The alkylating agents, ethylene and propylene oxides, are considered to inactivate bacteria and their spores by combining with amino, carboxyl, sulfydryl, and hydroxyl groups of proteins, as mentioned above.

The general antimicrobial activity of ethylene oxide (CH_2CH_2O) and related substances parallels their activity as alkylating agents (Phillips 1952). Thus, cyclopropane ($CH_2CH_2CH_2$), which is not an alkylating agent, is devoid of antimicrobial activity, whereas ethylene sulfide (CH_2CH_2S) and ethylene imine (CH_2CH_2NH) are potent alkylating compounds that demonstrate antimicrobial properties.

ACTION ON FUNGI

It is often assumed that the same effects as those in nonsporulating bacteria are responsible for fungal inactivation, but in view of the considerable structural and biochemical differences between these microbes this is undoubtedly an oversimplification. However, as with bacteria, it is likely that an initial interaction at the cell surface is followed by passage of a biocide across the fungal cell wall to reach its target site(s). Little information is available about the mechanisms of biocide uptake into fungal cells despite long-standing studies of biocide adsorption to yeasts and molds (Lyr 1987; Gadd and White 1989; Russell 1999c).

Although the fungal cell wall may be a prime target for developing new antifungal antibiotics (Hector 1993), few biocides are likely to have the wall as a sole target. Chitin has been suggested as a potentially reactive site for glutaraldehyde action in yeasts (Gorman and Scott 1977). Glutaraldehyde is also known to cause agglutination of yeast cells (Navarro and Monsan 1976).

Chlorhexidine induces K^+ release from bakers' yeast (Elferink and Booij 1974) and affects the ultrastructure of budding *Candida albicans* with the loss of cytoplasmic constituents (Bobichon and Bouchet 1987). Uptake of chlorhexidine by and membrane damage in *S. cerevisiae* have been described (Hiom et al. 1993, 1995a, b, 1996). The QACs also affect membrane integrity. Heavy metals probably bind to key functional groups of enzymes (Lyr 1987).

Very few relevant studies have been made on other target sites, but DNA and RNA would be expected to be targets for a number of biocides, such as cationic agents that interact strongly with nucleic acids (Hugo 1999b).

ACTION ON VIRUSES

The mechanisms whereby biocidal agents inactivate viruses are still poorly understood, although recent progress has been encouraging. In an excellent paper,

Grossgebauer (1970) discussed the possible effects of biocides on viruses and proposed that (a) water-saturated phenol caused separation of protein from infectious RNA in poliovirus; (b) low formaldehyde concentrations produced an antigenic but noninfectious particle (for use in a vaccine); and (c) higher aldehyde concentrations gave a noninfectious destroyed particle.

Thurmann and Gerba (1988, 1989) considered the possible interactions between viruses and biocides as being:

- adsorption to capsid receptors
- release of infectious nucleic acid
- destruction of capsid leading to release of infectious nucleic acid, or
- nucleic acid rendered noninfectious
- capsid remaining intact, but nucleic acid rendered noninfectious.

They pointed out that CRAs could inactivate viruses by attacking either capsid proteins or nucleic acid.

GTA reduces the activity of HBsAg and especially core antigen in HBV (Adler-Storthz et al. 1983) and interacts with lysine residues on the surface of hepatitis A virus (Passagot et al. 1987). Low concentrations (<0.1 percent) of alkaline GTA act against purified poliovirus, whereas poliovirus RNA is highly resistant to higher concentrations (Bailly et al. 1991). From this, it may be inferred that changes to the capsid are responsible for loss of infectivity. Support for this contention has been obtained by demonstrating that the capsid proteins of poliovirus and echovirus react with low concentrations (0.05 and 0.005 percent, respectively) of the dialdehyde, the ten-fold difference in aldehyde concentration probably reflecting major structural alterations in the two viruses (Chambon et al. 1992). Some biocides (hypochlorite, 70 percent ethanol and cetrimide) induce a rapid loss of the outer capsid layer, whereas chlorhexidine and phenol affect morphology only after extended periods of exposure (Rodgers et al. 1985).

Mechanistic studies of the effects of biocides on bacteriophages have been undertaken. These investigations (Maillard et al. 1995; Maillard and Russell 1997; Maillard 2001) have provided useful information about the interaction of biocides with phage protein and nucleic acid and on the inhibition of transduction, but much remains to be done to understand fully the mechanisms of inactivation.

ACTION ON PROTOZOA

Little is known about the mechanisms of antiprotozoal action of biocides, a disappointing gap in our knowledge and one that needs to be rectified. It has, however, been demonstrated (Khunkitti et al. 1997, 1998a, b, 1999) that chlorhexidine affects the membrane of trophozoites and cysts of *Acanthamoeba castellanii*, although cysts are less sensitive (Furr 1999).

Mechanisms of microbial resistance to biocides

Three levels, low, intermediate, and high, of biocidal activity have been recognized (Favero and Bond 1993). In high level, bacterial spores, fungi, mycobacteria, and viruses are inactivated; in intermediate level, mycobacteria, fungi, and viruses are inactivated; and in low level, nonsporulating bacteria (except mycobacteria) and lipid enveloped viruses are rendered nonviable.

Thus, different organisms vary considerably in their susceptibility to biocides (see Types of microorganism).

RESISTANCE OF NONSPORULATING BACTERIA

Vegetative bacterial cells respond to chemical and other stresses in a variety of ways that include the activation and expression of new groups of genes (Gould 1989). When *E. coli* is subjected to nutrient limitation or to antimicrobial agents, the growth rate decreases and gene expression is markedly altered (Gilbert et al. 1990c). This is essential for the long-term survival of cells and is partly mediated by alternative sigma factors such as σ^s encoded by the *rpoS* gene. Positive regulation of this expression results in σ^s synthesis being activated by guanosine 3′-diphosphate-5′-diphosphate (ppGpp). In an insertional mutant of *E. coli* that cannot produce σ^s, and in *E. coli* and other gram-negative organisms that produce ppGpp, the cells are more resistant to biocides and antibiotics than isogenic mutants (Greenaway and England 1999a, b). Tolerance to stress by hydrogen peroxide arises from intrinsic resistance mechanisms. The oxidative stress response involves the production of neutralizing enzymes to prevent cellular damage, with the SOS defense system response coming into operation when DNA damage takes place (Imlay 2002).

Drug efflux is a major mechanism involved in antibiotic resistance (Poole 2000, 2002; Levy 2002a, b). There are several types of efflux pumps: (1) P-glycoprotein, encoded by a human or rodent gene, mediated by ATP-dependent exporters, and a member of the ATP-binding cassette (ABC) superfamily of transporters, is responsible for resistance to many cytotoxic drugs; (2) small multidrug resistance family (SMR); (3) major facilitator superfamily (MFS); (4) resistance/nodulation/cell division family (RND), unique to gram-negatives and working in conjunction with a periplasmic membrane-fusion protein (MFP) and an outer membrane protein; and (5) multidrug and toxic compound extrusion (MATE) family. Families 2–5 are secondary transporters driven by the protonmotive force.

Enzymatic inactivation occurs at low biocide concentrations (Hugo 1991b) but is unlikely to be a problem with in-use concentrations, although Meade et al. (2001)

consider inactivation to be one mechanism of triclosan resistance in some bacteria.

Bacterial resistance mechanisms fall into two general categories. *Intrinsic resistance* (intrinsic susceptibility) is a natural propert of an organism, whereas *acquired resistance* results from genetic changes to a cell. This general concept (Table 5) has been of value but should perhaps be reconsidered because some biochemical mechanisms of resistance, e.g. efflux, can be associated with both types.

It has been known for many years that repeated exposure of bacterial cells to an antibiotic can result in stable bacterial resistance (Levy 2002a). It has also been demonstrated that bacteria also have this ability to acquire resistance to a variety of biocidal agents (Russell and Chopra 1996; Russell 1998a, 1999d, 2003a, b, c, 2004). The resistance thus developed may be low- to high-level, stable or unstable (in which there is reversion to susceptibility or the adaptive resistance is lost on removal of biocide). The clinical relevance of stable decreased susceptibility to biocides is a matter of conjecture. Cross-resistance to chemically related biocides occurs, but occasionally to chemically unrelated biocides nd to some antibiotics also (Tattawasart et al. 1999a, b, 2000a, b; Thomas et al. 2000; Lambert et al., 2001; Joynson et al. 2002; Lear et al. 2002; see below).

Biocides are generally considered to have concentration-dependent multiple actions on bacteria and other microbial cells. Thus, single mutations are unlikely to lead to large increases in biocide resistance to biocides. However, a mutation in the primary target site, enoyl reductase (FabI) in *E. coli* and *S. aureus*, might be the reason for the reduced susceptibility of these organisms to triclosan (McMurry et al. 1998b) (see also Mechanisms of action of antimicrobial agents).

Mycobacterial resistance

The mycobacterial cell wall is highly hydrophobic with a mycoylarabinogalactanpeptidoglycan skeleton. Thus, hydrophilic agents have difficulty in penetrating the wall in sufficiently high concentrations to achieve a mycobactericidal effect. Low concentrations must, however, traverse the wall because inhibitory concentrations of nonmycobactericidal agents such as chlorhexidine and QACs are generally of the same order as those against other, nonmycobacterial organisms (Russell 1996). The component(s) of the mycobacterial wall responsible for the high level of biocide resistance is (are) unknown, but both the mycolic acids and arabinogalactan may be involved (Broadley et al. 1995; Russell 1996). Acquired mycobacterial resistance by repeated exposure to a biocide is a possibility, but there appears to be no evidence that plasmids are involved.

The new aromatic cyclic dialdehyde, OPA (see Types and uses of chemical agents) is believed to readily traverse the cell wall of GTA-resistant *M. chelonae* strains, whereas the less hydrophobic GTA is unable to do so (Walsh et al. 1999a, b, 2001; Simons et al. 2000; Fraud et al. 2001, 2003).

Resistance of other nonsporulating gram-positive bacteria

The cell wall of gram-positive bacteria is a thick, fibrous layer pressed against the cytoplasmic membrane; the wall consists mainly of an inelastic peptidoglycan interspersed with which may be lipids and teichoic and teichuronic acids (Hammond et al. 1984). The peptidoglycan comprises at least 50 percent of the dry weight of the walls. Mechanisms whereby biocidal agents enter gram-positive bacteria have been little studied, but passive diffusion across the wall is probably a major factor. Thus, organisms such as staphylococci and streptococci are usually highly susceptible to biocides (Russell 1995, 1998b, 1999d, 2003a; Russell and Russell 1995; Russell and Chopra 1996). However, bacteria grown under different conditions may show a wide response to biocides. For instance, fattened cells of

Table 5 *Mechanisms of bacterial resistance to biocides* [a]

Bacteria	Mechanism(s) of Intrinsic resistance	Acquired resistance
Mycobacteria	Permeability barrier associated with hydrophobic cell wall	Not described, unlikely
Other nonsporulating gram-positive bacteria	Cell-wall modulation 1 Peptidoglycan changes 2 Lipid increase	Plasmid-mediated efflux of cationic biocides in multiple antibiotic-resistant *S. aureus*; enzymatic inactivation of Hg compounds
Bacterial spores	Permeability barrier associated with outer membrane	Not described, unlikely
	SASPs and DNA protection	Unlikely
Gram-negative bacteria	1 Reduced uptake associated with outer membrane permeability barrier and efflux	Enzymatic inactivation of Hg compounds; efflux of cationic biocides?
	2 Constitutive biocide-degrading enzymes?	?

a) For further information, see Russell and Russell (1995); Russell and Chopra (1996); Russell (1999a, 2003a) and following text.

S. aureus produced by repeated subculturing in glycerol-containing media are more resistant to benzylpenicillin and higher phenols (Hugo 1999a). Additionally, nutrient limitation and reduced growth rates (Gilbert et al. 1990a; Poxton 1993) can alter sensitivity to biocides by changes in peptidoglycan thickness and cross-linking. Such changes in these two examples can be regarded as the expression of intrinsic resistance brought about in response to a phenotypic (physiological) adaptation.

Acquired resistance is also known in some strains of *S. aureus*. Inorganic mercury (Hg^{2+}) resistance is a common property of clinical isolates of *S. aureus* containing penicillinase plasmids. These plasmids are either narrow-spectrum, specifying resistance to Hg^{2+} and some organomercurials, or broad-spectrum, encoding additional resistance to other organomercurials. The enzymes involved are mercuric reductase (Hg^{2+}) and lyase (hydrolase) and reductase (organo-compounds) (Foster 1983). Resistance to other metals has been described (Silver et al. 1989) and often involves efflux mechanisms. Silver (Ag^{+}) reduction may not form the basis of silver or silver sulfadiazine (AgSD) resistance (Belly and Kydd 1982; Foster 1983; Silver et al. 1989), but may be associated with accumulation (Trevor 1987; Russell and Hugo 1994).

Some methicillin-resistant strains of *S. aureus* (MRSA) containing plasmids encoding gentamicin resistance (methicillin–gentamycin-resistant *S. aureus*, MGRSA) also have increased minimum inhibitory concentration (MIC) values towards such biocides as QACs, chlorhexidine, ethidium bromide (EB), acridines, and propamidine isethionate (PI) (Lyon and Skurray 1987; Cookson and Phillips 1990; Cookson et al. 1991; Day and Russell 1999). Several genetic determinants are responsible for cationic biocide resistance in clinical isolates of *S. aureus*. There is evidence that there is an efflux of cationic agents from such antibiotic-resistant strains (Midgley 1986, 1987). Several genetic determinants are responsible for cationic biocide resistance in clinical isolates of *S. aureus*. These are *qacA*, which specifies resistance to QACs, acridines, EB, propamidine isethionate, and low-level chlorhexidine resistance; *qacB*, which is similar; *smr* (formerly *qacC/qacD/ebr*) encoding QAC and low-level EB resistance; and *qacG* and *qacH*. The corresponding gene products belong to the MFS (qacA, qacB) and SMR (smr, qacG, qacH) efflux families.

Resistance of gram-negative bacteria

Gram-negative bacteria such as pseudomonads and Enterobacteriaceae are usually less sensitive to a variety of chemically unrelated inhibitors than are gram-positive cocci. One reason for this lies in the different structural and chemical composition of the outer layers of the organisms, thereby conferring an intrinsic resistance mechanism on gram-negative bacteria. The cell envelope of gram-negative bacteria is more complex: the inner (cytoplasmic) membrane is adherent to the peptidoglycan which is covalently linked to Braun's elongated lipoprotein. The peptidoglycan–lipoprotein complex partly occupies the periplasmic space that exists between the outer and inner hydrophobic membranes.

The OM acts as a permeability barrier in limiting or preventing the entry of many chemically unrelated types of antibacterial compounds into gram-negative bacteria. Some antibacterial agents, e.g. polymyxins and possibly chlorhexidine and the QACs, damage the OM, thereby promoting their own entry into the cell (Hancock 1984).

Acquired chromosomal resistance by mutation has been described for chlorhexidine resistance with *P. stuartii* (Chopra et al. 1987) and *S. marcescens* (Lannigan and Bryan 1985), alcohols with *E. coli* (Fried and Novick 1973), and cationic bactericides with various organisms (Chopra 1987). Resistance is not always stable. Temporary resistance by phenotypic adaptation to alcohols is described by Chopra (1987), who also considers that, in general, a nongenetic adaptive type of resistance is unlikely to play an important part in determining the long-term survival of bacteria to antiseptics and disinfectants.

Strains of *P. stuartii* isolated from paraplegic patients often harbor plasmids conferring resistance to Hg^{2+} and several antibiotics and the organisms may also express resistance to cationic biocides. However, attempts to transfer chlorhexidine and QAC resistance to suitable recipients have failed and the occurrence of a plasmid-linked association between antibiotic and antiseptic resistance has not been substantiated.

High-level resistance to biocides has been observed in hospital isolates of other gram-negative bacteria but no clear role for plasmid-mediated biocide resistance (Russell 1985, 1997) has emerged in the following instances: (1) chlorhexidine- and antibiotic-resistant *P. mirabilis*; (2) chlorhexidine-resistant strains of *Burkholderia cepacia* and *Alcaligenes denitrificans*; and (3) chlorhexidine- and QAC-resistant *P. aeruginosa* and several members of the Enterobacteriaceae (Russell and Chopra 1996).

'Emerging' gram-negative bacteria that may prove to be of concern include *Acinetobacter* spp. Isolates of these organisms do not, however, appear to date to have a particularly high level of biocide resistance (Higgins et al. 2001; see also Weber and Rutala 1999; Rutala and Weber 2001a, b; Russell 2002a).

BACTERIAL SPORE RESISTANCE

Bacterial spores differ fundamentally in both structure and composition from vegetative cells. In essence, a spore usually consists of a central core (protoplast, germ cell) and germ cell wall surrounded by a cortex, external

to which are an inner and an outer spore coat (Foster 1994; Setlow 1994). Degradative changes take place during spore germination and biosynthetic processes during outgrowth (Paidhungat and Setlow 2002). Vegetative cells thus produced have the typical form and composition of nonsporulating bacteria (Russell 1990a).

Bacterial spores are amongst the most resistant of all microbial forms to inactivation by chemical or physical agents. Several factors contribute to this high resistance (Russell 1990a; Bloomfield and Arthur 1994; Bloomfield 1999; Loshon et al. 2001). These are (a) the thick, proteinaceous coats that limit the uptake of some biocides; (b) the reduced permeability of the spore core/protoplast to hydrophilic agents; (c) the protection of spore DNA by saturation with α, β-type (but not γ-type) small, acid-soluble proteins (SASP); and (d) the repair of DNA damage during germination. SASPs are basic proteins present in the spore core, but are rapidly degraded during germination. They play an important role in determining the response of bacterial spores to biocides. Spores ($\alpha^-\beta^-$) lacking such SASPs are much more sensitive to hydrogen peroxide and hypochlorites than parent spores (Tennen et al. 2000; Loshon et al. 2001).

Several studies (Power et al. 1988; Shaker et al. 1988; Knott et al. 1995; Cabrera-Martinez et al. 2002) have shown that during sporulation, an early resistance develops to formaldehyde, whereas resistance to chlorhexidine and QACs is an intermediate, and to glutaraldehyde and OPA a late, event.

BIOFILMS AND RESISTANCE

A biofilm is a consortium of bacteria or other microbes organized within an extensive exopolysaccharide exopolymer (glycocalyx: Costerton et al. 1987, 1994; Carpentier and Cerf 1993; Denyer et al. 1993; Poxton 1993). Biofilms may consist of monocultures, diverse species, or mixed phenotypes of a given species. Originally envisaged as homogeneous structures, biofilms are considered to be highly structured habitats with spatial and physiological heterogeneity (Wimpenny et al. 2000). Organisms can deposit enzymes within the matrix (Gilbert and McBain 2001a, b; Gilbert et al. 2002a, b) and cell-to-cell signalling (Davies et al. 1998; Swift et al. 2001) is an important feature in biofilm regulation, with the quorum-sensing systems of *P. aeruginosa* providing an excellent example (Wimpenny et al. 2000).

Attachment to surfaces is a vital element in bacterial infections, including those pertaining to medical devices (McBain and Gilbert 2001; Denyer 2002). Sessile bacteria on surfaces or present within biofilms are much less readily inactivated than planktonic cells (Carpentier and Cerf 1993; Poxton 1993; Donlan and Costerton 2002; Dunn 2002). Several reasons have been put forward for this difference. Early stress responses may be involved (see above). Diffusion of biocides into biofilms and interaction with biofilms are both important aspects (Gilbert et al. 2001; Stewart et al. 2001), but are not the only factors responsible. A biocide gradient is produced throughout the biofilm, so that in a thick biofilm there will be an 'in-use' concentration of biocide at the surface, but a greatly reduced concentration as the biocide penetrates into the community (Gilbert and McBain 2001b). Degradative enzymes might be more effective at these lower concentrations within a biofilm than against in-use concentrations acting on planktonic cells

A physiological gradient is also produced such that nutrients and oxygen will be consumed at the periphery of the biofilm with limits to both occurring within the deepest parts of a biofilm. Nutrient-depleted cells are less sensitive to biocides, so that greater numbers of biocide-resistant cells are present towards the interior of a biofilm where they are exposed to lower biocide concentrations. In addition, pockets of surviving organisms may occur as small clusters in biocide-treated biofilms, although neighboring cells have been inactivated (Huang et al. 1995). These might have arisen as a result of the occurrence of biocide and physiological gradients. The clusters might also contain mutants in addition to genotypes with modification in single gene products (Gilbert et al. 2002b).

Furthermore, sublethal treatment with a biocide could induce the expression of multidrug efflux pumps and efflux mutants. Thus, *mar* expression is greatest within the depths of a biofilm where growth rates are lowest (Maira-Litran et al. 2000).

Lewis (2000, 2001) has proposed that the inactivation of a cell does not occur as a result of the direct action of a biocide, but rather from programmed cell death (PCD). Persisters of such a programme are then regarded as cells deficient in PCD that can grow rapidly in the presence of exudate released from lysed community cells.

Thus, many complex factors contribute to the relative insusceptibility to biocides of cells within biofilm communities (Gilbert and McBain 2001a, b; Gilbert et al. 2001, 2002a). In addition to the factors outlined above, cellular impermeability of some types of bacteria will also play a role.

POSSIBLE LINKED BIOCIDE-ANTIBIOTIC RESISTANCE

Biocides and antibiotics share some common mechanisms or sites of action. Acridines, phenylethanol, phenoxyethanol, fluoroquinolones, and some β-lactams all induce filamentation in gram-negative bacteria (Ng et al. 2002), although not necessarily by the same means. However, no cross-resistance was found between the different chemical agents.

Another example occurs with triclosan and the antitubercular drug, isoniazid (isonicotinylhydrazine, INH) (McMurry et al. 1999). Triclosan inhibits enoyl reductase involved in fatty acid synthesis in gram-negative and

gram-positive bacteria (including mycobacteria), whereas INH has a specific effect on *M. tuberculosis* and some other mycobacteria. INH is essentially a prodrug that is converted into an active form by a *katG*-encoded oxidase-peroxidase system in *M. tuberculosis*, but not in other bacteria. Absence of this enzyme is the major mechanism for INH resistance in this organism. In *M. smegmatis*, mutations of the *inhA* gene that encodes a protein target (InhA) of INH involved in mycolic acid biosynthesis confers resistance to both INH and triclosan. Thus, the potential exists for the development of resistance to triclosan in mycobacteria to also be translated into INH resistance. However, it has not been demonstrated that triclosan is responsible for selecting for INH-resistant strains of *M. tuberculosis*.

Possible shared mechanisms of resistance to biocides and antibiotics are impermeability, uptake into gram-negative bacteria of cationic agents, mutations at a specific target site, enzymatic degradation, and extrusion (efflux) (Russell 1995, 2000, 2001c, 2002b, c, 2003a, b, c, 2004; Paulsen et al. 1996; Levy 2000, 2001, 2002a, b; Chuanchen et al. 2001; Health Council of the Netherlands 2001; Sulavik et al. 2001; Schweizer 2001; White and McDermott 2001; Fraise 2002a, b; Koljalg et al. 2002; Loughlin et al. 2002; Walsh et al. 2003a, b). Three biocidal types of agent, namely chlorhexidine, QACs, and triclosan, have been suggested as being involved in antibiotic resistance (Heir et al. 1998, 1999; Sundheim et al. 1998). Lambert et al. 2001 found that biocide/antibiotic-resistance in *P. aeruginosa* occurred especially in hospital, but not in industrial, isolates. However, antibiotic resistance resulted from the selective pressure exerted from antibiotic usage with no evidence that disinfection procedures produced biocide-resistant organisms. In a subsequent study (Joynson et al. 2002), it was demonstrated that an organism, *P. aeruginosa*, that is resistant to a common biocide (the QAC, benzalkonium chloride) could become sensitive to an antibiotic, whereas the converse was not true.

Veterinary clinical isolates of *P. aeruginosa* are resistant to high levels of triclosan, carbenicillin, and tetracycline, all of which are good substrates for the MexAB-OprM efflux system (Beinlich et al. 2001). In an earlier study (Chuanchen et al. 2001), ciprofloxacin resistance had been shown to be possibly associated with triclosan resistance, the phenylether inducing an efflux system. However, this fluoroquine antibiotic is a marginal substrate for this efflux system but a better substrate for MexCD-OprJ and MexEF-OprN (Beinlich et al. 2001).

S. aureus strains are commonly highly sensitive to triclosan (MICs around 1 μg/ml). However, some (but not all) clinical isolates, including MRSA strains, have elevated MICs of 1–2 μg/ml but do not necessarily show antibiotic resistance and are not killed less rapidly than triclosan-sensitive strains by higher concentrations of this compound (Suller and Russell 1999, 2000). VRE (Hiramitsu 1998) are not more resistant to biocides than are vancomycin-sensitive strains (Alqurashi et al. 1996; Day and Russell 1999).

Paulsen et al. (1998) proposed that *qacA* had evolved from *qacB*, that benzalkonium chloride (a QAC) induced the expression of *qacA* and *qacB*, and that their chronological emergence in clinical isolates of *S. aureus* mirrored the introduction and usage of cationic biocides in hospitals. Akimitsu et al. (1999) have claimed that QAC-resistant mutants of MRSA strains show greatly increased resistance to some β-lactam antibiotics.

Ishikawa et al. (2002) suggested that after *E. coli* had mutated to resist a relatively low concentration of a QAC under laboratory conditions, it could be converted to a multidrug-resistant type. However, whilst several authors have shown an association between biocide and antibiotic resistance in laboratory experiments, the 'real-life' situation is more difficult to assess. Currently, it must be stated that the evidence of a linkage between biocide usage and clinical antibiotic resistance is far from proven (Russell 2000; Gerba and Rusin 2001; Gilbert and McBain 2001a; McBain and Gilbert 2001). Antibiotic resistance is far more likely to occur as a result of the inadequate and improper usage of these drugs in clinical practice and their incorporation into animal feed. Many different acquired genes resposible for resistance of gram-negative bacteria to many antibiotics are part of gene cassettes that can move into or out of companion elements (integrons) (Hall and Collis 1998).

The possible role of biocide rotation in preventing biocide resistance from developing in hospitals has been considered by Murtough et al. (2001).

FUNGAL RESISTANCE

Two basic mechanisms of fungal resistance to biocides can be envisaged: intrinsic and acquired (Dekker 1987; Russell 1999d). The fungal cell wall contains various types of polymers, including chitin and chitosan (Zygomycetes), chitin and glucan (mycelial forms of ascomycetes and deuteromycetes), and glucan and mannan (yeast forms of ascomocytes and deuteromycetes). Thus, there is ample opportunity for a cell to exclude biocide molecules. Studies on the sensitivity of *C. albicans* to the polyene antibiotic, amphotericin, suggests that glucan may have a role to play in limiting drug uptake (Gale 1986). Comparable studies with biocides are sparse, but there is tentative evidence that glucan, but not mannan, in yeast cell walls could have a role to play in limiting chlorhexidine uptake (Hiom et al. 1993, 1995a, b, 1996).

There is no evidence linking the presence of plasmids in fungal cells and the ability of the organisms to acquire resistance to fungistatic or fungicidal agents, although acquired resistance of yeasts to organic acids is known (Warth 1986, 1989).

VIRAL RESISTANCE

Conflicting results have been reported about the action of biocides on different types of viruses. In part, this can probably be explained on the basis of different methodologies. However, the penetration of biocides into viruses and phages of different types has not been examined in depth, nor has interaction with viral protein and nucleic acid. It is, therefore, difficult to provide adequate reasons to explain the relative response, or resistance, of different virus types to biocides. Nevertheless, some progress has been made on the basis of the scheme of Klein and Deforest (1983), as described in Types of microorganism. Thurmann and Gerba (1988) suggested that the structural integrity of a virus is altered by an agent that reacts with viral capsids to increase viral permeability. A 'two-stage disinfection' could offer an efficient means of viral inactivation whilst overcoming the possibility of multiplicity reactivation first put forward in 1947 to explain an initial reduction and then an increase in titer of biocide-treated bacteriophage.

RESISTANCE OF PROTOZOA

The cyst form represents the stage in the life cycle that is resistant to biocides. Only a few significant studies have been undertaken about biocide sensitivity or resistance during encystment and excystment and the relative uptake of biocides into cysts and trophozoites. It has been shown that resistance develops as encystment proceeds and is lost during excystment of *Acanthamoeba castellanii*. It may be concluded that the outer regions of cysts limit entry of biocides, thus providing one mechanism of intrinsic resistance (Khunkitti et al. 1997, 1998a, b, 1999; Turner et al. 1999, 2000a, b; Lloyd et al. 2001).

PHYSICAL AGENTS AND OTHER STERILIZATION METHODS

Physical agents (Table 6) are normally used in preference to chemical agents for sterilization, either by microbial destruction or by removal of microorganisms (Dewhurst and Hoxey 1990; Soper and Davies 1990; Kowalski 1993; Russell 1993, 1999d, 2001a, b; Denyer and Hodges 1999; Hoxey and Thomas 1999). It is also practicable, however, to employ cold, desiccation, and freeze-drying as methods of preservation. Traditionally, heat in one form or another has been employed as a sterilization procedure. It still occupies a key role and is the method of choice whenever possible. Filtration is also based on ancient knowledge but suffers several limitations. Ionizing radiation is widely used for the sterilization of single-use, disposable items. Newer procedures employ various types of gas plasmas.

Moist heat

Heating in the presence of water has long been used as a method of sterilization, or sometimes of disinfection. It can be employed in different ways, e.g. at temperatures below, at, or above 100°C.

TERMINOLOGY

Thermal death time (TDT) is the time (in minutes) required to kill all cells in a suspension at a given temperature. Thermal death point (TDP) is the temperature needed to kill all cells in suspension after a

Table 6 *Types and applications of sterilization processes* [a,b]

Process	Application(s)
Moist heat (autoclave)	Sterilization of many ophthalmic and parenteral products, surgical dressings, rubber gloves (high-vacuum autoclave)
Flash sterilization	Modification of conventional steam sterilization
Dry heat	Sterilization of glassware, glass syringes, oils and oily injections, metal instruments; depyrogenation at high temperatures
Infrared radiation	Sterilization of heat-resistant instruments (high temperature responsible)
Ionizing radiation	Sterilization of single-use disposable medical items
Ultraviolet radiation	Poor sterilizing agent; use restricted to air sterilization (in conjunction with air filtration) and water disinfection
	Surface sterilization
Pulsed light (non-ionizing radiation)	
Ethylene oxide	Sterilization of fragile, heat-sensitive equipment, powders, components of spacecraft
Low-temperature steam with formaldehyde (LTSF)	Disinfection/sterilization of some heat-sensitive materials
Filtration	Air sterilization; sterilization of thermolabile ophthalmic and parenteral solutions, and of sera
Gas plasmas	

a) See text for information about most important processes.
b) Chemical agents such as glutaraldehyde and peroxygens are sometimes employed as 'chemosterilizers.'

fixed exposure time, e.g. 10 min. There are many variables associated with these terms, notably inoculum size, and as such they are usually of little value.

The *D* value (decimal reduction time, DRT), is the time (in minutes) needed at a particular temperature to reduce the viable organisms by 90 percent, i.e. to 10 percent or by 1 $\log_{10}$ unit. *D* value is independent of inoculum size and is related inversely to temperature. Examples are given in Table 7.

Inactivation factor (IF) is the degree of reduction in the number of viable cells and is obtained by dividing the initial viable count (N_0) by the final viable count (N_u), i.e. IF = N_0/N_u. An alternative procedure is to use the *D* value approach; IF = $10^{t/D}$ (in which *t* represents the treatment dose, i.e. time). There are, however, pitfalls with this method (Russell 1982).

The *z* value, defined as the number of degrees (°C) to bring about a 10-fold reduction in TDT or *D* value, is obtained from the slope of the curve in which temperature is plotted against time (see Russell 1982). An alternative method is based on a knowledge of the temperature coefficient (Q_{10}) per 10-fold rise in temperature, i.e. $Q_{10} = 10^{10/z}$ from which z = 10/log Q_{10}.

The *F* value is the time in minutes to destroy an organism in a specified medium at 121°C (250°F). F_0 is the *F* value when $z = 10$°C (18°F). Calculations employing F_0 values are used in validating thermal sterilization processes (Soper and Davies 1990).

Exponential rate of inactivation is depicted in Figure 2(A). Deviations from this occur frequently (Figure 2(B, C, D): Cerf 1977; Smerage and Teixeira 1993; Stringer et al. 2000). With convex- or concave-type curves, extrapolation of the line to cut the *Y*-axis gives the *Y*-intercept value (Y_0). If N_0 represents the initial number of cells, then (1) when $Y_0 = N_0$, there is a straight line response; (2) when $Y_0 > N_0$, there is an initial shoulder; (3) when $Y_0 < N_0$, a decreasing death rate is obtained.

The intercept ratio (IR) is a ratio of the two values, i.e. IR = log Y_0/log N_0, and is thus useful in characterizing time–survivor curves.

MICROBIAL SENSITIVITY TO MOIST HEAT

Nonsporulating bacteria are heat-sensitive and are usually destroyed at temperatures of 50–60°C (Russell 2003b). Thermal death times of fungi and protozoa are similar and most viruses are inactivated at 60°C for 20 min (Russell 1999d). *D* and *z* values for some bacterial spores are listed in Table 7.

Bacterial spores are considerably more resistant to moist heat. Among *Bacillus* spp., *B. stearothermophilus* is the most heat-resistant. Considerable variation in sensitivity occurs among *Clostridium* spp., *C. botulinium* type E being far more sensitive than types A, B or C (Russell 1982, 2003d).

Sensitivity to moist heat depends on the conditions of exposure and recovery. In medical, surgical, and veterinary practice, microorganisms are often embedded in organic debris, which may to some extent insulate them from the effect of heat, and thorough cleaning prior to sterilization is essential (Roberts 2001).

TYPES OF MOIST HEAT PROCESSES

Temperatures below 100°C

During his studies on spoilage of French wines, Louis Pasteur employed a temperature of 60°C. Subsequently, this process (60°C for 30 min) was used for the pasteurization of milk. A 'flash' method (71.1°C for 15 s) was introduced later. A procedure similar to pasteurization has been employed in the production of certain bacterial vaccines, e.g. typhoid vaccine, the aim being to kill the organisms while preserving their immunogenicity.

Although some types of spore are killed by moist heat at about 80°C, temperatures below 100°C cannot be relied upon to achieve sterilization.

Temperatures around 100°C

These temperatures cannot be relied upon to kill bacterial spores, and steaming is thus of limited use. Two variations have been used. The first (tyndallization) involved steaming for 30 min (originally 80°C for

Table 7 *Responses* [a] *of some bacterial spores to heat and to ionizing radiation*

	Moist heat		Dry heat		Ionizing radiation (D)	
Bacterial spore	**D (min) at 121°C**	***z***	**D (min) at 160°C**	***z***	**Mrad**	**kGy**
Bacillus stearothermophilus	4–5	8–10	<1	15–25	...	...
B. subtilis	<1	5.5–9.5	1–5	20	0.15	1.5
B. cereus	<1	...	...	20	0.1	1
B. pumilus	...	...	...	25	0.2	2
Clostridium sporogenes	<1	10	2	20	0.15–0.2	1.5–2
C. botulinum type A	<1	9.5	...	...	0.1	1

a) Values are approximate responses to a particular process. The actual response will depend upon several parameters (see text and Russell 1982, where comprehensive details are provided). *D*, time (min) at a specified temperature or radiation dose needed to reduce the viable population by 1 $\log_{10}$ unit; *z*, temperature (°C) needed to reduce the *D* value by 90 percent.

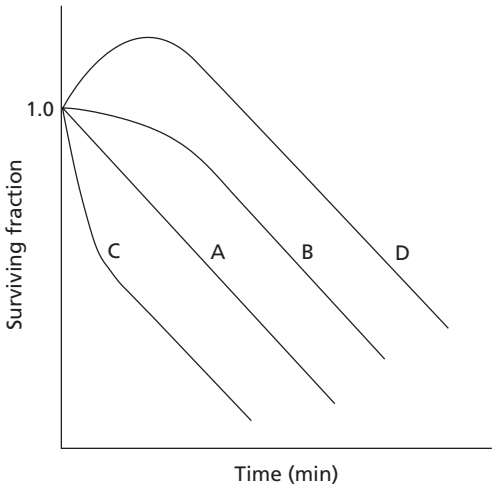

Figure 2 *Thermal inactivation curves of bacterial spores. A, exponential death; B, increasing death rate; C, decreasing death rate; D, heat activation.*

60 min) on each of 3 consecutive days, the principle being that spores that survived a heating process would germinate before the next thermal exposure and would then be killed. Spores will not, however, germinate in a non-nutrient medium and, although this process was originally an official method for sterilizing injections, it is no longer used. The second variation involved heating to 98–100°C in the presence of a specified antimicrobial agent (the activity of which is considerably potentiated at the high temperature; see Factors influencing activity). This method is no longer permitted in the British Pharmacopoeia (1988, 1993, 1998, 2000) for sterilizing any injectable or eyedrop formulations.

Temperatures above 100°C (autoclaving)

Sterilization by steam under pressure depends upon four properties of dry saturated steam: high temperature, wealth of latent heat, ability to form water by condensation, and instantaneous contraction in volume that occurs during condensation. These properties are optimal only in steam on the phase boundary between itself and condensate at the same temperature (Figure 3). Steam formed at any point on the phase boundary has the same temperature as the boiling water from which it was derived. However, it holds an extra, and relatively heavy, load of latent heat, which, without a drop in temperature, is available instantly and entirely as soon as it wets a cooler surface.

Superheated steam is hotter than dry, saturated steam at the same pressure, the process becoming akin to dry heat, which is much less efficient. Superheated steam behaves as a gas and only slowly yields its heat to cooler objects. In Figure 3, steam at any point A on the phase boundary is saturated: if, however, the temperature is raised to B (keeping pressure constant), then superheated steam is generated. A small amount (5°C) of superheat may be tolerated in practice.

When air is present in a space with steam, the air will carry part of the load so that the pressure of the steam is reduced, creating a condition equivalent to that defined by the horizontal line AC in Figure 3. This can also be deduced from Dalton's law of partial pressures, which, applied to the present context, can be written as $P_{total} = P_{steam} + P_{air}$. The removal of air is, in fact, important in ensuring efficient autoclaving and can be achieved in various ways. In downward-displacement sterilizers, air is displaced downwards, being heavier than steam; this process may, however, be wasteful of steam and time-consuming. Its widest application is in the sterilization of bottled fluids (Owens 1993). Bulky packages of, for example, surgical dressings are, however, air-retentive and the downward-displacement method of removing air is not efficient. Removal of air before admission of steam is far more effective and can be achieved by the use of high prevacuum autoclaves or by means of a pulsed evacuation and steam admission. Thermal processing is also widely employed in the food industry (Brown 1994; Gould 1999). Table 8 lists the time–temperature relationships provided by the British Pharmacopoeia (2000). Sterilizers designed for bottled fluids generally employ temperatures of 121°C and those for porous loads 126–134°C.

Flash sterilization

Flash sterilization is a modification of conventional steam sterilization. In this process, a flashed item is placed unwrapped in an open mesh tray or in a specially designed rigid container to allow for rapid penetration of steam. Either gravity or prevacuum autoclaves can be used for this purpose (Barrett 2001).

Low-temperature steam with formaldehyde

Low-temperature steam (LTS) at subatmospheric pressure was developed originally for disinfecting heat-

Table 8 *Permitted time–temperature relationships in moist-heat and dry-heat sterilization processes* [a]

Process	Temperature (°C)	Holding period (min)
Moist heat (autoclave)	121	15
	126	10
	134	3
Dry heat	Minimum of	Not less than
	160	120
	170	60
	180	30

a) Based on recommendations in British Pharmacopoeia (2000).

sensitive materials. LTS at 80°C was found to be much more effective than water at the same temperature. The addition of formaldehyde to LTS to produce low-temperature steam with formaldehyde (LTSF) achieved a sporicidal effect (Dewhurst and Hoxey 1990; Soper and Davies 1990), and LTSF is thus suitable for sterilizing thermolabile equipment, although there are now doubts about the efficacy of this process.

MECHANISMS OF MICROBIAL INACTIVATION BY MOIST HEAT

Heat induces a multiplicity of injuries in sporing and nonsporing bacteria (Russell 2003b), and every cellular component (outer layers, membranes, enzymes, proteins, RNA, DNA) is likely to be affected to some degree. In thermophiles and hyperthermophiles, enzymes and proteins are much more heat-stable (Madigan et al. 1997) because of critical amino acid substitution in one or a few locations. It is thus unlikely that the lethal effect can be attributed to a single event in an organism.

In nonsporulating bacteria, mild heat treatment (approximately 45–50°C) damages the outer membrane of *E. coli*, rendering cells more sensitive to hydrophobic inhibitors (Hitchener and Egan 1977; Mackey 1983). Lethal damage occurs to the cytoplasmic membrane with RNA breakdown and protein coagulation (Tomlins and Ordal 1976) and damage to the bacterial chromosome (Pellon and Sinskey 1984). Virtually all structures and functions can be damaged by heat, but repair to non-DNA structures can occur only if DNA remains functional, thereby providing the necessary genetic information. DNA is implicated in heat damage, directly or as a result of enzymatic action after thermal injury (Pellon and Sinskey 1984). Using repair-deficient *E. coli* mutants, Mackey and Seymour (1987) proposed that heat-induced DNA damage occurred indirectly via an oxidation mediated by hydrogen peroxide (or free radicals derived from it) in peroxide-generating complex recovery media. Their results also provide a satisfactory explanation for 'minimal medium recovery,' which appears to involve protection from this peroxide-induced effect. By potentiating the effectiveness of DNA repair systems, *Deinococcus radiodurans* (see Physical agents and other sterilization methods) has an extraordinary ability to withstand the lethal and mutagenic effects of DNA-damaging treatments. A relationship exists between bacterial sensitivity to ionizing radiation and mild heat shock, and *D. radiodurans* is considered to be a heat-resistant organism (Battista et al. 2000).

The bacterial cell senses exposure to heat by means of:

- Extracellular alarmones by switching on inherent tolerant mechanisms. Extracellular sensing components (ESC) are directly converted into extracellular induction components (EIC), with very rapid responses occurring at increasing levels of stress (Rowbury 2001).
- Inducible intracellular heat-shock proteins (HSP) Hecker and Volker 2001). In *E. coli*, most genes require the sigma factor σ^{70} for transcription. Genes induced by heat shock have different sequences and RNA polymerase (RNAP) requires σ^{32} to recognize them. The amount of this alternative sigma factor regulates the heat-shock response. σ^{32} is encoded by *rpoH*, which specifically directs RNAP to transcribe from the heat-shock promoters (Polissi et al. 1995; Yura et al. 2000).

In bacterial spores (Figure 2), thermal injury has been attributed to a variety of reasons. These include denaturation of vital spore enzymes, impairment of germination or outgrowth or both, membrane damage (leading to leakage of calcium dipicolinate), increased sensitivity to inhibitory agents, structural damage (as observed by electron microscopy), and damage to the spore chromosome (as evinced by mutations or DNA strand breaks). Effects on DNA are much more pronounced during dry heating (see section on Dry heat); which generates a high level of mutants in spore populations (Gould 1989). DNA is, however, an important target, although the exact mechanism of spore inactivation is unknown. Deficiencies in DNA repair mechanisms are known to render spores more heat-sensitive (Hanlin et al. 1985). SASPs are of two types, the α,β-type associated with spore DNA, and the γ-type, not associated with any spore macromolecule. Spores lacking α,β-type SASPs are more susceptible than wild-type spores to moist heat (Setlow 1995). The DNA in these mutants is more sensitive, with a high frequency of single-strand

breaks (Setlow and Setlow 1996). Spore proteins have also been implicated (Belliveau et al. 1992; Setlow 1994), although the nature of these is unclear.

MECHANISMS OF RESISTANCE OF BACTERIAL SPORES TO MOIST HEAT

The resistance of spores to heat can be manipulated over several orders of magnitude by exposure to extreme pH values and cationic exchange treatment (H-form and Ca-form, respectively) (Alderton and Snell 1963; Alderton et al. 1980). The content and location of water in spores play important roles in their heat resistance. Spores have a low water content (see below) and this is an essential factor in resistance. Spore coats do not contribute to thermal resistance since coatless spores are not more heat-sensitive than ordinary spores. Gould and his colleagues (reviewed by Gould 1989) found that resuspension of newly germinated spores in high concentrations of sucrose or sodium chloride (but not of glycerol) restored resistance to heat and ionizing radiation. In such an osmoregulatory mechanism the cortical structure would have to maintain a uniform pressure upon, and thereby control, the water content of the spore core.

Warth (1985) considered three types of mechanisms that might contribute to the stability of proteins in the spore. They could be intrinsically stable; substances might be present that help stabilize them (there is no strong evidence to support this notion but calcium dipicolinate may play a role); and the removal of water could alter their stability. A direct role for dipicolonic acid (DPA) seems unlikely, but it might help establish and maintain dormancy and heat resistance (Tovar-Rojo et al. 2002).

Several spore properties are, in fact, important for heat resistance, notably protein thermotolerance, dehydration, mineralization, thermal adaptation, and cortex function (Murrell 1981; Beaman and Gerhardt 1986; Beaman et al. 1988, 1989; Gerhardt and Marquis 1989; Marquis et al. 1994, 1995). In addition, SASPs found in the spore core have some role to play. Spores lacking α/β-type SASPs are more sensitive than wild-type spores and it is likely that heat-induced DNA damage is the mechanism involved (Setlow 1994). However, these SASPs are not a major determinant of spore resistance to moist heat because heat resistance during sporulation is attained well after their synthesis (Setlow 1994; Setlow et al. 2001).

The single most important factor contributing to spore resistance to moist heat is the reduced water content of the spore core, with other factors playing a supporting role (Setlow 2000).

Dry heat

Dry heat is a less efficient sterilization process than moist heat. The terminology used in describing moist heat sterilization is also employed here. Bacterial spores are the most resistant organisms to dry heat and D and z values are much higher than for moist heat (Table 7) (Wood 1993; Russell 1999e, 2003d).

TYPES OF DRY HEAT PROCESSES

Normally, dry-heat sterilization takes place in hot-air ovens, a number of combinations of temperature and time being permitted (Table 8). It is essential that the hot air can circulate between objects being sterilized, which must therefore be loosely packed with adequate air spaces to ensure optimum heat transfer. A fan is essential to prevent the wide variation in temperature that would otherwise occur. Industrially, sterilization equipment can also consist of forced-convection ovens, rapid heat-transfer sterilizers, and continuous-belt sterilizers (Wood 1993). Dry-heat sterilization (Table 6) is the method of choice in the pharmaceutical industry for many heat-stable objects and materials (Dewhurst and Hoxey 1990) and at higher temperatures it can also destroy pyrogens (depyrogenation; Wood 1993). The use of infrared ovens has been described (Mata-Portuguez et al. 2002).

MECHANISMS OF MICROBIAL INACTIVATION BY DRY HEAT

Microbial inactivation by dry heat has been considered primarily an oxidation process. Spores heated in oxygen would thus be expected to be more sensitive than when heated in the presence of other gases, but this is not necessarily true (Pheil et al. 1967). Thus, although oxidation may play an important part, other possibilities must be considered.

An effect on DNA is one possibility (Setlow 1994), sublethal temperatures inducing mutants in *B. subtilis* spores (Zamenhof 1960) as a consequence of depurination (Northrop and Slepecky 1967). The water content of spores is an important factor in determining inactivation by dry heat. Rowe and Silverman (1970) postulated that only a relatively small amount of water is needed to protect the heat-sensitive site in spores and that resistance to dry heat depends mainly on the location, rather than on the amount, of water in the spore, and on its association with other molecules.

Inactivation by cold

Growth of microorganisms is retarded and eventually ceases if they are held at reduced temperatures. Some can grow at temperatures approaching 0°C and these psychrophiles may be important food-spoilage organisms. Environmental factors such as nutrient status, pH, salt concentration and a_w (water activity or moisture content) can alter the minimum growth temperature (Herbert 1989).

Freeze-drying involves rapid freezing with subsequent drying in a vaccum and is used widely for preserving microbial cultures and certain foodstuffs, but its use subjects microorganisms to stresses such as freezing, drying, storage, and eventual rehydration (Mackey 1984). Single-strand breaks in DNA and an increase in the frequency of mutation may be caused by freeze-drying (Asada et al. 1979).

Freezing and thawing can inactivate bacteria. Damage to the outer and inner membranes envelope has been shown in *E. coli* (Mackey 1983, 1984). For comprehensive accounts, the papers by MacLeod and Calcott (1976) and Mackey (1984) should be consulted.

Cold shock is a process in which organisms are suddenly chilled without freezing. Gram-positive and gram-negative bacteria, but not yeasts, may be killed (MacLeod and Calcott 1976; Rose 1976). Several factors influence the response of cells, notably the age of the culture (exponential phase, but not stationary phase, cells being susceptible) and the composition of the medium. Divalent cations can protect cells against chilling. Low-molecular-weight materials are released from chilled cells as a consequence of increased membrane permeability caused by a phase transition in membrane lipids (Rose 1976). A modification of this treatment is 'cold osmotic shock,' in which bacteria are suspended in a hypertonic sucrose solution containing EDTA and are then suspended in ice-cold magnesium chloride solution. This treatment does not kill the cells but does induce the release of periplasmic enzymes, including β-lactamases, from gram-negative bacteria.

Hydrostatic pressure

Some organisms can exist at the bottom of deep oceans where they are subjected to high pressure (Dring 1976). Bacterial spores are more resistant to hydrostatic pressure than are germinated spores or nonsporulating bacteria. Temperature profoundly affects bacterial sensitivity to hydrostatic pressure, the rate of inactivation increasing as the temperature rises. This combined effect can be potentiated if an additional heat treatment is given after pressurization (Gould, 1970; Gould and Jones, 1989; see also New low-temperature sterilization technologies). The application of hydrostatic pressure is a useful technique because it enables investigations to be made of germination in the absence of physiological germinants. In view, however, of the occurrence of 'superdormant' spores (Gould et al. 1968), which are resistant to hydrostatic pressure, it is unlikely that this process will find use as a sterilization procedure.

Ionizing radiation

Ionizing radiations, e.g. X-rays, γ-rays, and high speed electrons (β-rays), strip electrons from the atoms of the material through which the radiations pass; essentially all the chemical changes produced in the microbial cell are due to these stripped-off electrons, which initiate a chain of chemical reactions. Ionizations occur principally in water, resulting in the formation of short-lived but highly reactive radicals (hydroxyl, •OH) and protons (H^+). Single-strand, and sometimes double-strand, breakage in DNA ensues. By contrast, ultraviolet (UV) radiation does not possess enough energy to eject an electron to produce an ion, although there is an alteration of electrons within their orbits. It is not therefore an ionizing radiation. Infrared radiations rapidly raise the temperature of objects that they strike and are thus employed for their heating effect. X-rays and γ-rays are of very short wavelengths and are generated by machines or radioactive sources (e.g. ^{60}Co). High-speed electrons were originally produced from radioactive isotopes but had little penetration; various machines have been developed that accelerate atomic particles to give them the energies for penetrating deeply. X-rays and γ-rays have considerable penetrating power. By contrast, α-particles, which consist of helium nuclei ($^4_2$He), have little penetration and thus are not used for sterilization. Industrially, radioisotopes in the form of ^{60}Co (Herring and Saylor 1993) and accelerated electrons (Cleland et al. 1993) are the main sources of ionizing radiation.

The unit of radiation most widely used in microbiology was previously the rad, a measurement of the energy absorbed from ionizing radiation by the matter through which the radiation passes. The newer, more modern (SI) unit is the gray (Gy; 1 Gy = 100 rad), which is defined as the deposition of 1 J/kg energy in tissue.

MICROBIAL SENSITIVITY TO IONIZING RADIATIONS

Bacterial spores are generally more resistant than nonsporulating bacteria, although *D. radiodurans* is the most resistant organism known (Moseley 1989; Russell 1999f). Among the clostridia, *C. botulinum* types A and B are the most resistant, type E being highly sensitive. Among *Bacillus* spp., *B. pumilus* E601 is probably the most resistant (see Table 7). During bacterial sporulation, resistance to γ-radiation develops about 2 h before the onset of heat resistance (Durban et al. 1970). Although spore-coat disulfide bonds were believed to be radioprotective, it is now clear that the –S–S-rich protein structure does not afford resistance, since coatless spores are as resistant as normal spores (Hitchins et al. 1966; Gould and Sale 1970; Farkas 1994).

MECHANISMS OF MICROBIAL INACTIVATION BY IONIZING RADIATIONS

Ionizing radiations induce structural defects in microbial DNA, which, unless repaired, are likely to inhibit DNA synthesis, leading to cell death (Hutchinson 1985). DNA

is not the only target relevant to inactivation, although it is undoubtedly the principal one (Lindahl 1982), with single-strand breaks (SSB) and double-strand breaks (DSB) depending on the intensity of the radiation dose (Moseley 1989).

The state of DNA in the cell is important in relation to bacterial inactivation. Spores are generally more resistant to ionizing radiation than are nonsporing organisms. There are several possible reasons, notably that:

- spores contain a radioprotective substance (but there is no evidence to support this supposition)
- spore coats confer protection, but coatless spores are not less resistant
- DNA is present in a different state in spores.

DNA in bacterial spores exists in the A-form, associated with a low a_w value, and it is certainly true that DNA in the intact spore is more resistant to SSBs and DSBs than DNA in the intact vegetative cell. However, DNA extracted from spores shows the same response in vitro to ionizing radiation as DNA extracted from nonsporulating bacteria. Furthermore, newly germinated spores exposed to ionizing radiation in an environment of high osmotic pressure again become radiation-resistant (Gould 1983, 1984, 1985). Damage to DNA is less extensive under such circumstances.

α/β-type SASPs have some role to play in conferring heat resistance on spores, presumably by stabilizing DNA; however, neither they nor γ-type SASPs are involved in ionizing radiation resistance (Setlow 1994).

MECHANISMS OF MICROBIAL REPAIR FOLLOWING IONIZING RADIATION

Several microorganisms show above-average resistance to ionizing radiation (and to UV radiation, see section on Ultraviolet radiation) because they possess enzymes capable of repairing damage to DNA (Bridges 1976; Moseley 1984, 1989). Repair has been widely studied in *D. radiodurans* and in *E. coli* mutants in which sensitivity to ionizing radiations is conferred by genes such as *rec (A, B, C)*, *polA*, and *lon*.

SSBs in bacterial spores can be repaired during post-irradiation germination (Terano et al. 1969, 1971). In *C. botulinum* 33A, which is highly radiation-resistant, direct repair (rejoining) of SSBs takes place during or after radiation in spores existing under nonphysiological conditions at 0°C and in the absence of germination (Durban et al. 1974). Such repair of SSBs within these dormant, ungerminated spores may result from DNA ligase activity (Gould 1984).

USES OF IONIZING RADIATION

Ionizing radiation has found particular use as a means of sterilizing single-use medical devices (Russell 1999f). Food irradiation has long been considered as a means of sterilizing or preserving food (Russell 1999f) but has met with considerable consumer resistance.

Ultraviolet radiation

UV radiation has a wavelength of approximately 328–210 nm. Its maximum bactericidal effect is documented at 240–280 nm (Sykes 1965). Modern mercury-vapor lamps emit more than 95 percent of their radiation at 253.7 nm, which is at or near the maximum for microbicidal activity. The quantum of energy liberated is low, and consequently UV radiation has less penetrating ability and is less effective than other types of radiation. It is not, therefore, considered as being an effective method of sterilization (Russell 1993, 1999g).

MICROBIAL SENSITIVITY TO UV RADIATION

Bacterial spores are generally more resistant to UV light than are vegetative cells (an exception being *D. radiodurans*: Battista 1997), although mold spores may be even more resistant. Viruses are also inactivated; they tend to be more sensitive than bacterial spores, but are often more resistant than nonsporulating bacteria (Morris and Darlow 1971). HIV is not inactivated by UV radiation (Report 1986).

MECHANISMS OF MICROBIAL INACTIVATION BY UV RADIATION

Exposure of nonsporulating bacteria results in the formation of purine and pyrimidine dimers between adjacent molecules in the same strand of DNA (e.g. the forward reaction in Figure 4a). The photoproduct, 5,6-hydroxydihydrothymine, is also found in *D. radiodurans* exposed to ionizing and UV radiation (Figure 4b). In bacterial spores, another type of photoproduct, 5-thyminyl-5,6-dihydrothymine (TDHT) (Figure 4c) accumulates in DNA. A less well-known and less frequent photoproduct, pyrimidine (6,4) pyrimidone, is the relevant lesion involved in the toxic and mutagenic effects of UV on *E. coli* (Mitchell and Nairn 1989; Koehler et al. 1996). Unless removed, photoproducts form noncoding lesions in DNA and bacterial death results.

MECHANISMS OF MICROBIAL REPAIR IN NONSPORULATING BACTERIA

The SOS network, controlled by the RecA and LexA proteins, is responsible for the expression of genes whose products play roles in radiation-induced excision, daughter strand gap, and DSB repairs. There are three major mechanisms that are involved in repair of UV-induced DNA damage:

1. Photoreactivation (light repair), in which the exposure of UV-irradiated cells to light of a higher wavelength, but below 510 nm, results in the induction of a photoreactivating enzyme that monomerizes thymine

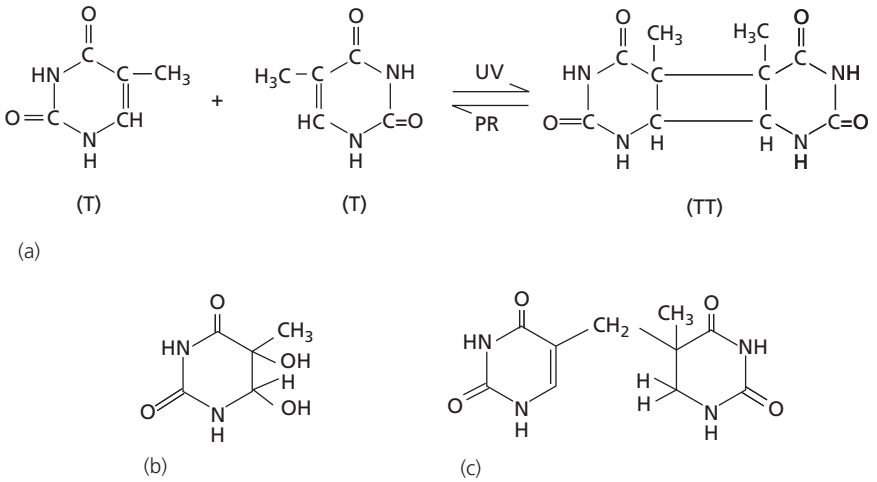

Figure 4 *Ultraviolet (UV)-induced changes in DNA:* **(a)** *pyrimidine dimer formation and reversal (photoreactivation, PR);* **(b)** *5,6-dihydroxydihydrothymine;* **(c)** *5-thyminyl-5,6-dihydrothymine (TDHT). T, thymine; TT, thymine dimer.*

dimers in situ (Figure 4a, reverse direction) and results in the recovery of a large proportion of cells that would otherwise have been inactivated (Moseley 1989; Russell 1999g).

2 Dark repair (excision), in which the stages are first, the action of a dimer-specific endonuclease, which 'nicks' the DNA; second, a dimer-specific exonuclease, which excises the damaged portion together with a number of nucleotides on each side, followed by the action of DNA polymerase I; and, finally, DNA ligase, which is responsible for the final joining together.

3 Dark repair (post-replication recombination), in which replication proceeds normally until it reaches an unexcised dimer, which is a noncoding lesion. A gap is left opposite the dimer and replication recommences at a new initiation site some 800–1000 bases downstream. Because dimers occur in both parental strands of DNA, both daughter strands contain gaps, which are repaired by recombinational insertion of parental DNA from the sister duplex. The process requires a functional recA gene product. Recombination-deficient mutants are abnormally sensitive to UV and ionizing radiations.

For additional information on repair, mutants and error-prone repair, see Bridges (1976), Moseley (1984, 1989), and Sancar and Sancar (1988).

MECHANISMS OF MICROBIAL REPAIR IN BACTERIAL SPORES

The spore photoproduct, TDHT, is identical to one that accumulates in hydrolysates of DNA exposed dry, or as a frozen solution, to UV radiation (Rahn and Hosszu 1968; Varghese 1970). With the exception of *D. radiodurans*, vegetative cells in the frozen state are supersensitive to UV and a photoproduct (presumably TDHT) other than thymine dimers accumulates, which is less susceptible to repair. UV-sensitive mutants of UV-resistant *B. subtilis* spores form the same photoproduct (TDHT) and to the same extent for a given dose of radiation as do the resistant spores. UV resistance is thus linked to the ability to remove TDHT (Munakata and Rupert 1972), and two genetically controlled mechanisms have been described (Munakata and Rupert 1972, 1974):

1 'Spore repair' involving the elimination of TDHT during germination, although vegetative growth is not required

2 Excision repair, in which TDHT disappears slowly from the large-molecular-weight trichloracetic acid (TCA)-insoluble fraction and appears in the TCA-soluble fraction.

PRACTICAL USES OF UV RADIATION

UV radiation has little penetrative power through solids and is extensively absorbed by glass and plastics. Sterilization is achieved only by doses of radiation beyond the limits of practicability. It does, however, have some use as a disinfection procedure. It has been used to disinfect drinking water (Sykes 1965); as a possible means of obtaining pyrogen-free water; and especially for air disinfection, notably in hospital wards and operating theaters, in aseptic laboratories and in ventilated safety cabinets in which dangerous microorganisms are being handled (Morris and Darlow 1971).

Sunlight also has disinfecting properties, rays of wavelengths 254–257 nm possessing the greatest bactericidal activity. It has been claimed that sunlight can inactivate *B. anthracis* spores on wooden and metal surfaces, although only after prolonged exposure. Infectivity of viruses may be reduced on exposure to direct sunlight (Russell et al. 1984).

Sterilization by filtration

Filtration in various forms was used in ancient times, e.g. in attempts to purify water and sewage by allowing it to percolate through beds of sand, gravel, or cinders. These and other applications are considered by Denyer and Hodges (1999) and Jornitz et al. (2002), who also describe the development of modern filtration devices.

TYPES OF FILTER

Several types of filters are used, including (1) *unglazed ceramic filters*, e.g. the Chamberland and Doulton filters, which are manufactured in several different grades of porosity and have been used industrially for the large-scale clarification of water. After use, they can be cleaned with sodium hypochlorite solutions and will withstand scrubbing; (2) *compressed diatomaceous earth filters*, examples of which are the Berkefeld and Mandler filters, which are manufactured in different grades of porosity. They have been used industrially for the large-scale clarification of water. After use, they can be cleaned with sodium hypochlorite but without scrubbing; (3) *asbestos filters*, which include Seitz, Carlson, and Sterimat filters. They have high adsorbing capacities and tend to alkalinate solutions being filtered. There is also a possibility of toxic effects (including carcinogenesis) in handling these filters and they are now practically obsolete; (4) *sintered glass filters*, which are prepared by size-grading finely powdered glass followed by heating. The pore size can be controlled by the general particle size of the glass powder. The filters are easily cleaned, have low adsorption properties, and do not shed particles, but they are fragile and relatively expensive; (5) *membrane filters*, which consist of cellulose esters. They are used routinely in water analysis and purification, sterilization, and sterility testing and are the most suitable for preparing sterile solutions for parenteral use. Membrane filters are available in a range of pore sizes from approximately 12 μm down to 0.5 μm, sterilizing filters usually having an average pore diameter (APD) of 0.2–0.22 μm. The ratio of maximum pore diameter (MPD) to APD is in general 3.5–5. Membrane filters have several advantages over conventional depth filters (Denyer and Hodges 1999).

High-efficiency particulate air (HEPA) filters remove particles of 0.3 μm or larger (and probably particles <0.1 μm) (Denyer and Hodges 1999) and are widely used in air filtration, especially that type incorporating laminar air flow (LAF) (White 1990). LAF units are of two types, horizontal and vertical, depending upon the direction of the air flow.

MECHANISMS OF STERILE FILTRATION

Membrane filters are often described as 'screen' filters in contrast to media such as sintered glass, asbestos fiber, and ceramic, which are believed to retain organisms and particles by a 'depth' process in which particles are trapped or adsorbed within the interstices of the filter matrix. Screen filtration, on the other hand, has been considered to exclude (sieve out) all particles larger than the rated pore size. However, it is now apparent that the filtration characteristics of many membrane filters cannot be accounted for in terms of the sieve retention theory alone, but that other factors are involved, including van der Waals' forces and electrostatic interactions.

Additional information is provided by Lukaszewicz and Melzer (1979), Tanny et al. (1979), and Denyer and Hodges (1999).

APPLICATIONS OF FILTRATION

Filtration can be used for sterilization of thermolabile parenteral and ophthalmic solutions, sterility testing of pharmaceutical products, clarification of water supplies, microbiological evaluation of water purity, viable counting procedures (including estimation of survivors following exposure to antibiotics or disinfectants), and for determination of viral particle size (see also Table 6). For most of these applications, membrane filters are usually employed.

Additionally, filters are used in air sterilization, including LAF cabinets as described above.

New low-temperature sterilization technologies

Several new low-temperature procedures have been described in recent years that have proved to be useful sterilization procedures.

GAS PLASMAS

Low-temperature hydrogen peroxide gas plasmas are generated by applying radiofrequency waves to hydrogen peroxide vapor. The vapor is broken up into reactive free radicals that form the gas plasma (Groschel 1995; Jacobs and Lin 2001). This gas plasma is sporicidal and is eventually broken down to oxygen and water (Rutala and Weber 2001a).

Low-temperature plasma sterilizers that utilize ion plasmas formed from peracetic acid have also been described (Alfa et al. 1998).

LIQUID STERILIZATION SYSTEMS

New liquid sterilization systems have been described that are proving to be of benefit in sterilization of some medical devices. These include automated machines that utilize peracetic acid for the sterilization of lensed flexible and rigid endoscopes (Groschel 1995; Holton et al. 1995; Alfa et al. 1998).

Performic acid, a new proprietary liquid sterilant, is part of a new automated endoscope-reprocessing system

(Rutala and Weber 2001a). It is formed by mixing the two component solutions, hydrogen peroxide and formic acid.

Combined synergistic treatments

Enhanced antimicrobial efficacy is often achieved by combining two or more processes, chemical or physical. There are various types of combined treatment (Gould and Jones 1989).

THERMOCHEMICAL TREATMENT

The antibacterial activity of a compound usually increases as the temperature rises (see Factors influencing activity). This was exemplified by using certain preservatives at high temperatures in the sterilization of certain injectable and ophthalmic products (Russell 1999a), although this process is no longer approved. The gaseous sterilant ethylene oxide is also employed at higher temperatures (approximately 60°C) and LTSF has been claimed to be a useful sterilization procedure. In the food industry, acid–heat treatment is an important method of sterilization (Gould and Jones 1989).

CHEMICAL TREATMENT AND IRRADIATION

The presence of various chemicals during irradiation may either sensitize bacterial spores to, or protect them from, the consequences of ionizing radiation. Spores are more sensitive under oxic than under anoxic conditions. Ketonic agents of widely differing electron affinities sensitize spores suspended in anoxic buffers to subsequent radiation, although the maximum sensitization achieved is only about 40 percent of that in oxygen alone (Tallentire and Jacobs 1972). Sensitizing agents appear to act by removing electrons from the conversion of •OH to OH^-, which is harmless to the spore.

THERMORADIATION

Thermoradiaton is the simultaneous use of heat and ionizing radiation. Careful selection of temperature is, however, important because a 'paradoxical inversion' or 'thermorestoration' occurs at certain temperatures; for example, with *C. botulinum 33A* spores, there is an increase in sensitivity above 80°C (Grecz 1965).

OTHER COMBINATIONS

Other combined processes that have been examined include hydrostatic pressure combined with heat or radiation (Wills 1974), ultrasonic waves with GTA (Boucher 1979), and combinations of chemicals (Russell 1982).

Process validation, monitoring, and parametric release

It is important that strict control measures are employed to validate and monitor the efficacy of sterilization processes. In addition, sterility tests on samples of a batch of treated product are necessary (Favero, 1998; British Pharmacopoeia 2000), although undue reliance should not be placed on such tests alone.

Process validation (Favero 1998) is a means of demonstrating that a process actually works, i.e. that it kills (or removes) microorganisms, thereby achieving what it purports to do (achieve sterilization). For this reason, the choice of a test organism is important: it must possess above-average resistance to the process in question, although it need not necessarily be the most resistant organism known. Biological indicators (BI) in the form (usually) of bacterial spores are used to validate those processes designed to inactivate microbes. *D. radiodurans* is even more resistant to ionizing radiation than spores (see Ionizing radiation). It is not, however, used as a BI for this process because (a) it is not a normal contaminant (bioburden) on pharmaceutical or medical products and (b) its inactivation would require unacceptably high radiation doses that could damage many such products. Examples of BIs are provided in Table 9.

The principle involved in validating sterile filtration is to use a smaller-than-average test organism. If this is retained by the filter, then larger organisms also will not pass through the filter.

Table 9 *Validation and monitoring of sterilization processes*

Process	Validation[a]	Monitoring[b,c]
Moist heat	*B. stearothermophilus*	Temperature recording charts; thermocouples; CI
Dry heat	*B. subtilis* var. *niger*	Temperature recording charts; thermocouples; CI
Ionizing radiation	*B. pumilus*	Dosimeters; CI
Ethylene oxide	*B. subtilis* var. *niger*	Temperature probes; relative humidity; *B. subtilis* var. *niger*
Filtration	*S. marcescens*; *P. diminuta*	Bubble point pressure test

a) In addition to the biological indicators listed, the desired physical and chemical conditions to achieve sterilization must also be validated, e.g. measuring devices for heat, dosimeters for radiation, physical methods for determining filter integrity and temperature, and relative humidity for gaseous sterilization.
b) CI, chemical indicator (used as a visual check that a sterilization process has been undertaken: a color change does not necessarily mean that sterilization has been achieved).
c) Samples taken at random from a batch may also be subjected to sterility testing.

In addition to validating a process with BIs, it is also necessary to measure and record the required physical or chemical conditions reached throughout the sterilization cycle within every part of the load (Habarer and Wallhaeusser 1990).

Routine monitoring of a process is carried out by appropriate physical methods, except for ethylene oxide where difficulties still occur (Table 9). Sterility can then be assessed, except with ethylene oxide, by monitoring only the physical conditions of the process. Such a system (parametric release) is defined as the release of sterile products based on process compliance to physical specification (Dewhurst and Hoxey 1990).

Sterility assurance level (SAL) is a term employed to provide an expected level of safety with a sterilization process. It is generally accepted that terminally sterilized products, i.e. those sterilized in their final containers, have a safety level (SAL) of not more than one unsterile article per 10^6 items processed (Habarer and Wallhaeusser 1990; Bruch 1993; Graham and Boris 1993). SAL is thus based upon a sound knowledge of microbial inactivation kinetics, rather than upon sterility testing, which can detect only gross contamination.

PHILOSOPHY OF ANTIBACTERIAL USE

Prospects for the future

At the start of the twenty-first century, more than 250 antibacterial agents are in use throughout the world. With such an abundance at the prescribers' disposal it might be imagined that bacterial infection has become a minor problem and that bacterial drug resistance would be unable to keep pace with resources available to counteract it. Nothing could be further from the truth. Bacteria appear to possess a limitless ingenuity in avoiding the effects of antimicrobial agents, as well as in finding new ways to invade the compromised host. Moreover, mutations conferring resistance to one antibiotic can, at a stroke, render a whole drug family impotent. Bacteria resistant to one sulfonamide or one tetracycline are usually resistant to all sulfonamides, or all tetracyclines; 'methicillin-resistant' staphylococci are resistant to all β-lactam antibiotics. Even worse, bacteria can assemble resistance genes for unrelated classes of agents on integrons and plasmids that can be readily transmitted between bacterial species or, sometimes, genera.

For these reasons it is unwise to be complacent about our ability to control infection. Resistance is a serious global problem that must be countered by discriminating use of antimicrobial agents by all prescribers, by vigorous application of control of infection measures in health care institutions, and at government level by effective regulation of drug production, distribution, and use (European Union Conference 1998; Gould et al. 2000).

Ecological issues

Antibiotic use is huge with estimates as much as 100 000 tons/year worldwide, the majority of this in farming including veterinary use, growth promotion, crop spraying, and fish farming (Levy 2002; Harrison and Lederberg 1998). Potentially there is significant environmental pollution as much antibiotic is excreted in active form in urine and feces and is stable for prolonged periods (weeks to months) in the environment (Harrison and Lederberg 1998). No doubt this pollution revisits us through the food-chain in the form of antibiotic residues, antibiotic-resistant bacteria, and their resistant-determinate genes contaminating food. The scope of the problem has only been investigated on a very superficial basis.

It seems likely, nevertheless, that with a few notable exceptions, most of the antibiotic-resistant bacteria that cause problems in human medicine are generated by use of antibiotics in human medicine. Within human medi-

cine, the intensity of antibiotic use is greatest in the hospital and this is where (magnified by crossinfection) the most significant problems are seen (Gould 1999, 2002a). Within intensive care units (ICU), these problems of crossinfection and intensity of use are further magnified and even added to, by increasingly invasive and immunosuppressive diagnostic and therapeutic procedures. It is no surprise then that ICUs are considered the genesis units for the creation, maintenance, and dissemination of multiply-resistant bacteria (Gould 2002b).

Community antibiotic use is much less intense, although greater in overall volume (Cars et al. 2001). While the limited data available suggest not much difference in usage patterns between different hospitals across Europe, when case mix is taken into account, community use between different countries differs up to fourfold, tending to be lowest in northern Europe (Harbarth et al. 2002). A European average is approximately one prescription per head of population per year. Some countries have managed to lower community prescribing in the past few years with the help of educational campaigns directed both at doctors and their patients and concentrating on reducing the demand for and use of antibiotics for self-limiting respiratory tract infection which are usually viral in origin (Department of Health 2000).

In most countries of the industrially developed world, antibiotics used in human and veterinary practice are presently available only on prescription. It is most important that this status is maintained if resistance problems are to be kept under control. In developing countries where regulation of pharmaceutical products is generally more lax, more responsible national drug policies need to be enforced. The World Health Organization is actively engaged in promoting rational policies of drug use, but much remains to be done. One important initiative has been the formulation of an essential drug list which is updated at regular intervals (World Health Organization 1995). Only a handful of antibacterial agents appear on this list (Table 1); significantly, there are no cephalosporins or quinolones on the main list, emphasizing the restricted need for these extensively promoted and commonly prescribed drugs.

How use relates to resistance

While it is often said that there is little absolute proof that antibiotic use causes resistance, the link has been well established in numerous studies at individual patient level, group level such as family or day care center, in hospitals, community medical practices, regions, and whole countries (Baquero et al. 2002). The association applies to all antibiotics and bacteria but not to all bug/drug combinations. *Streptococcus pyogenes*, for example, has famously failed to become resistant to penicillins. Even here, however, while strains still yield the same minimum inhibitory concentration (MIC) of penicillin as they did 60 years ago there is some evidence of tolerance developing to the bactericidal activity of penicillins (Slater and Greenwood 1983). The speed of development of resistance and its degree will depend on many things. Probably most important will be the mechanism of action of the antibiotic and the ease with which the bacteria can develop resistance, e.g. bactericidal antibiotics, by eradicating a pathogen, are probably less likely to select resistance than bacteriostatic agents which will merely suppress division (Stratton 2003). If the bacterial strain has a high yield of resistant mutants or resistance spreads easily on plasmids then resistance will, presumably, arise and even spread easily. Intensity of use, spread by crossinfection, high inoculum infections, and immunosuppression are other factors likely to lead to rapid selection and/or

Table 1 *Antibacterial agents (excluding topical agents) on the World Health Organization's list of essential drugs (WHO 1995)*

Main list			
Penicillins	**Other antibacterial agents**	**Antimycobacterial agents**	**Complementary list[a]**
Amoxycillin[b]	Chloramphenicol	Clofazimine	Chloramphenicol (oily suspension)
Ampicillin	Co-trimoxazole[b]	Dapsone	Ciprofloxacin
Benzathine penicillin	Doxycycline	Ethambutol	Clindamycin
Benzylpenicillin	Erythromycin[b]	Isoniazid	Nalidixic acid
Cloxacillin[b]	Gentamicin[b]	Pyrazinamide	Nitrofurantoin
Phenoxymethylpenicillin	Metronidazole[b]	Rifampin	Trimethoprim
Piperacillin[b]	Spectinomycin	Rifampin + isoniazid	Thioacetazone + isoniazid (antimycobacterial)
Procaine penicillin	Sulphadimidine[b]	Streptomycin	
	Tetracycline[b]		

a) For use when drugs on the main list are known to be ineffective or inappropriate for a given individual, or for use in exceptional circumstances (e.g. chloramphenicol oily suspension in epidemics of meningitis) when the health services are overwhelmed. The need for additional reserve agents, e.g. a cephalosporin or vancomycin, is acknowledged.
b) Example of a therapeutic group for which acceptable alternatives exist.

spread of resistance and these are all factors operating in hospitals (Gould 1999; Gould and MacKenzie 2002). Long term, low-dose penicillin therapy has been shown to select efficiently for penicillin resistance in pneumococci (Guillemot et al. 1998). Patients receiving prior trimethoprim or amoxicillin for urinary and chest infections are several times more likely to have antibiotic-resistant infections if they present again within a few months (Steinke and Davey 2001). Within hospitals, most organisms causing problems of hospital-acquired infection (HAI) are selected by intensive antibiotic use; extended spectrum beta-lactamase (ESBL) producing *Klebsiella* by third generation cephalosporins (3GC) (MacKenzie and Gould 1998), derepressed *Enterobacter* and *Citrobacter* by 3GC (Wagenlehner et al. 2002), quinolone-resistant coliforms by quinolones (Scheld 2003; Kern et al. 1994), methicillin resistant *Staphylococcus aureus* (MRSA) by 3GCs, quinolones and macrolides (Monnet 1998; Monnet et al. 2004). In most cases, the organisms are resistant to the antibiotics selecting for them. Things may become more complicated in future as integrons, coding for multiple antibiotic-resistant determinants, are well dispersed in European hospitals (Gruteke et al. 2003; Leverstein-van Hall et al. 2003).

Can resistance be controlled?

It has long been assumed that if the high use of antibiotics is reversed, bacteria will normally return to their susceptible state. There is, however, no clear answer to this as it is usually a multifactorial issue (Austin et al. 1999). There are many examples in the literature, both in communities and hospitals where resistance problems have been reversed (although not necessarily returning to zero) when antibiotic use is controlled (Austin et al. 1999). Generally, resistance problems fall more quickly in hospitals than in the community because of the dilutional effect of patient discharge. Nevertheless, there are examples in the literature where control of use fails to reverse resistance problems and there may be many other cases where such negative results have not been published (Bonhoeffer et al. 1997). Mathematical models and in vitro experiments suggest that bacteria can rapidly learn to carry resistance without too much cost so that in many cases the resistance may be stable, even in the absence of the selection pressure of antibiotic prescribing (Bowler et al. 1994). Similarly, if a virulent clone becomes resistant, it may spread without the need for antibiotic selection pressure. Other factors to consider have been discussed above. Nevertheless, the consensus is that if antibiotic use is inappropriate it is correct to reduce it. If the high use is associated with a resistant problem then it will probably recede along with the reduction in use, but the role of crossinfection should also be addressed, particularly in healthcare institutions.

Antibiotic stewardship

Every healthcare institute and primary care practice should have an antibiotic formulary (list of antibiotics easily available and which the doctors should be familiar with) and antibiotic guidelines (details of diagnosis and treatment for specific infections) (Gould et al. 1994; Gould 2001; Keuleyan and Gould 2001). Within any region it is helpful if the formulary and guidelines are drawn up in consultation between primary and secondary care. Their primary aim is to act as an educational tool for doctors to improve their prescribing and in the UK and USA, most hospitals and primary care centers will have them (Gould et al. 1994; Shlaes et al. 1997; Gould 2001; Keuleyan and Gould 2001). There is also helpful guidance available on design and implementation of guidelines (www.agreecollaboration.org).

The formulary is a good basis for pharmacists to work to, only stocking formulary agents and within this list, monitoring the use of key 'restricted' agents, often with the help of infection specialists with an interest in prescribing. Inappropriate prescriptions can then be targeted with an educational intervention to limit inappropriate use (Solomon et al. 2001). In the near future it is hoped that electronic prescribing will allow easier monitoring of prescriptions (Burke and Pestotnik 1996). Other measures of a restrictive or educational nature that have variable success include special antibiotic order forms, automatic stop orders, therapeutic substitution, antibiotic rotation (or cycling) (Gould et al. 1994; Gould 2001; Keuleyan and Gould 2001; Shlaes et al. 1997), although the evidence base for these measures is often questionable. Currently, there are two Cochrane groups assessing the literature in this area in hospitals and primary care (Arnold 2004; Brown 2004). Help on assessing the effectiveness of interventions is available at www.abdn.ac.uk/hsru/epoc/. There is an increasing tendency to appoint pharmacists and microbiologists with a special interest in antibiotic therapy to monitor quality of use and to create multidisciplinary teams with hospital executive authority (Saizy-Callaert et al. 2003; Fluckiger et al. 2000).

Particular problems of antibiotic use differ between primary and secondary care. In primary care it tends to be unnecessary use for minor, self-limiting bacterial or viral respiratory infections (Steinman et al. 2003a, b; McCaig et al. 2003) . In secondary care it is often too much use of powerful broad spectrum, injectable antibiotics without any evidence of serious infections (Kumarasamy et al. 2003). These are often continued for too long and added to irrationally if the patient does not respond (spiralling therapeutic empiricism) (Kim and Gallis 1989).

Whereas use of the laboratory is relatively rare when treating infection in primary care it could (arguably) be increased (Shackley et al. 1997). Providing specimens

reach the laboratory the same day, it might be possible to give useful preliminary results the next day for the great majority of specimens. In most cases, even where antibiotic is thought to be indicated by the primary care doctor, the patient will not come to any harm waiting overnight to see if culture indicates that one is really needed. With modern electronic links, results can easily be communicated to the doctor the following morning (MacKenzie et al. 2003). In secondary care the laboratory is used much more, but clinicians are often reluctant to act on the results, e.g. streamline successful therapy, even with susceptibility results from clinically significant bacterial growths to guide them (Kumarasamy et al. 2003). They are, generally, even more reluctant to stop therapy early in the presence of negative cultures which may be strong evidence of a nonbacterial etiology for a patient's illness (Lawrence et al. 1973; Bartlett et al. 1991). Much is written about the importance of rapid molecular methods to guide clinicians in the therapy of infectious diseases. Much more efficient use, however, could be made of conventional test results, the great majority of which can be made available in a useful clinical timeframe: antigen tests, Gram stain, microscopy all within an hour, 6-h urine culture, Gram stain of blood cultures – 90 percent positive within 24 h, other specimen preliminary cultures available overnight. Conventional susceptibility testing methods can often give good indications of the best agents to use within 6–12 h, although final results take longer to read (NCCLS, 2000, 2002).

Good clinical liaison by the laboratory is crucial and there is an increasing tendency for microbiologists to undertake clinical consultations and ward visits to report on positive blood cultures, make daily visits to ICU, other high dependency units, and hematology/cancer wards to discuss important results and confirm correct choice of therapy.

General principles of use of antimicrobial agents for treatment and prophylaxis

The general principles underlying the choice of antimicrobial agents in infection are discussed by Lambert and O'Grady (1997), Finch (1995), and Keuleyan and Gould (2001). In brief, antibiotics should be used therapeutically only after thorough clinical assessment of the need, whenever possible on the basis of laboratory evidence of infection. Factors to be considered should include: the type of infection; the age and condition of the patient; the local prevalence of resistance (in the absence of specific laboratory guidance); the pharmacological properties of the agent in its various formulations; the likelihood of adverse reactions; possible interactions with other medications; and cost. Antimicrobial agents should be used for chemoprophylaxis only in individuals in whom the risk of infection is high. The agents chosen should be reliably active against the organisms likely to be encountered and use should be confined to the period of greatest risk (Slack 1995b).

A helpful definition of appropriate antibiotic therapy might include the following: (1) Appropriate antibiotic prescribing should potentially benefit the patient. (2) There should be clinical evidence, supported where possible by laboratory tests of bacterial infection. (3) Sepsis parameters should be documented and should support the need for antibiotic treatment. (4) Critical patients should receive appropriate treatment as quickly as possible. (5) Treatment should be limited to bacterial infections, using antibiotics directed against the causative agent, given in optimal dosage, interval, and length of treatment, with steps taken to ensure maximum patient compliance with the treatment regimen and only when the benefit of treatment outweighs the individual and global risks. (6) Antibiotic therapy should be streamlined at the earliest opportunity using the results of laboratory tests where possible (Gould 2001). There is an increasing number of evidence-based guidelines on the prophylaxis and treatment of infectious diseases now available (www.sign.ac.uk; www.cochcrane.org).

Pharmacodynamics of antibiotics (the effect of antibiotic concentration)

Over the past 20 years great strides have been made in understanding how to optimize antibiotic treatment by varying dose and dosing interval. This not only improves patient outcome, but also reduces the likelihood of selecting resistant strains during therapy. The study of pharmacodynamics (the effect of concentration) developed from a knowledge of the pharmacokinetics of different antibiotics (that is, the concentration achieved at different target sites) and the realization that antibiotics act in different ways. In particular, some antibiotics are primarily concentration dependent in their mode of action, most importantly the aminoglycosides and quinolones (Gould 1998; Drusano 2003). This has led us away from traditional three or four times daily administration of gentamicin to once daily administration to optimize its bactericidal effect. In addition, aminoglycosides and quinolones have a prolonged suppressive effect on regrowth of surviving bacteria (post antibiotic effect (PAE)) which allows a safe period of several hours of subinhibitory concentrations before it is necessary to give the next dose. Conveniently this also appears to ameliorate toxicity which is more dependent on high trough than high peak concentrations, due to the uptake of aminoglycosides by sensitive renal, vestibular, and cochlear cells being concentration limited (Mingeot-Leclecq and Tulkens 1999). Finally, high peak concentrations appear to be important in preventing

selection of resistant mutants which otherwise might arise during therapy and cause treatment failure (Blondeau et al. 2001; Zhao and Drlica 2001; Scheld 2003).

A great deal of work has been carried out recently on the mutant prevention concentration of new quinolones against pneumococci and other bacteria. Although purely theoretical at the moment, it is probable that this work will lead to further reassessment of dosing schedules for quinolones, where mutants selected during therapy appear to be the only way of resistance arising. In the meantime, dosing schedules of quinolones are considered flexible and in general terms can either be given one or two times daily despite widely varying half-lives. The single most important pharmacodynamic predictor of both clinical and microbiological success is achieving an area under the curve inhibitory concentration (AUIC) >125 (AUIC = AUC_{0-24}/MIC) (Thomas et al. 1998).

Other antibiotics, most importantly the β-lactam drugs and macrolides are time-dependent drugs. Once the concentration at the site of infection is above the MIC there is usually little advantage in increasing concentration further. Most of the antibacterial effect will be determined by the duration of exposure. Animal experiments suggest optimal effects if the concentration is maintained above the MIC ($T > \text{MIC}$) for approximately 50 percent of the dosing interval, although this figure is probably lower for most gram-positive infections and higher for gram-negative infections because of the absence of a significant PAE in the latter. For life-threatening or high inoculum infection, such as meningitis, where the host immune response is limited and for more resistant organisms, it is possibly safer to try to ensure $T > \text{MIC}$ for the whole dosing interval and to aim for concentrations around 8× MIC to ensure maximum bactericidal effect.

Antimicrobial drug combinations

The use of combinations of antimicrobial agents is increasing but makes more likely the risk of adverse reactions from the antibiotics themselves and from interactions with other drugs that the patient may be receiving. They include use of combination therapy in tuberculosis and leprosy; use of compounds that interact synergically to achieve improved bactericidal activity in certain serious infections, notably cystic fibrobsis and infective endocarditis; use of combinations to achieve adequate cover of mixed infections or in the 'blind' therapy of serious undiagnosed sepsis and lastly, treatment of infections that are already multiresistant to prevent selection of further resistant mutants. Thus, combinations are frequently used for MRSA infections and particularly when rifampin or fucidin is used as resistant mutants are known to arise easily to these agents when used alone. Such a strategy has been very successful over the years with tuberculosis.

CLASSIFICATION OF ANTIBACTERIAL AGENTS IN CLINICAL USE

Since antibacterial agents exhibit a very wide variety of properties, the simplest way to categorize them is according to their site of action in the bacterial cell: agents acting on the bacterial cell wall; agents acting on bacterial protein synthesis; agents acting on nucleic acid synthesis; and agents acting on the bacterial cell membrane (Table 2).

AGENTS ACTING ON BACTERIAL CELL WALL SYNTHESIS

The bacterial cell wall is a structurally unique feature that is absent from mammalian cells and is thus a prime target for selectively toxic agents. The cell wall of gram-negative organisms is very different from that of gram-positive bacteria and the complex of lipopolysaccharide and lipoprotein that forms the gram-negative outer-membrane confers properties of differential permeability that have a profound effect on the susceptibility to antibacterial agents of all kinds (Nikaido and Vaara 1985;

Table 2 *Classification of antibacterial agents according to their site of action*

Cell wall synthesis	Protein synthesis	Nucleic acid synthesis	Cell membrane
Penicillins	Aminoglycosides	Sulphonamides[a]	Polymyxins
Cephalosporins	Chloramphenicol	Diaminopyrimidines[a]	Gramicidin
Carbapenems	Tetracyclines	Quinolones	Tyrocidine
Other β-lactams	Macrolides	Rifamycins	Valinomycin[b]
Glycopeptides	Lincosamides	Nitroimidazoles	Monensin[b]
Bacitracin	Fusidic acid	Nitrofurans	
Cycloserine	Streptogramins	Novobiocin	
Fosfomycin	Mupirocin		
Isoniazid	Ketolides		
	Oxazolidinones		
	Glycylcyclines		

a) Indirect action on nucleic acid synthesis.
b) Not used in human medicine.

Hancock and Bellido 1992). Within the gram-negative outer membrane are hydrophilic channels (porins) that allow the differential passage of many agents whose target is the underlying peptidoglycan. Permeation of these porin channels by β-lactam antibiotics depends on molecular size and ionic charge and these factors may strongly influence the spectrum of activity and potency (Nikaido 1985). Glycopeptides are too large to penetrate the gram-negative outer membrane and consequently their spectrum of activity is virtually restricted to gram-positive organisms.

β-Lactam antibiotics

STRUCTURE

Antibacterial agents that share the structural feature of a β-lactam ring are now known to be very diverse. The classic penicillins are penams, characterized by a fused heterocyclic structure composed of a β-lactam ring and a five-membered sulfur-containing thiazolidine ring. In the cephalosporins the fused dihydrothiazine ring has an extra carbon with an unsaturated bond between C-3 and C-4, giving a cephem structure. The cephamycins are similar, but the β-lactam ring is substituted with a methoxy group which confers stability to many β-lactamase enzymes. Other structural variants represented among clinically useful compounds are: carbapenems, carbacephems, oxacephems, clavams, sulfones, and monocyclic monobactams (Figure 1).

MODE OF ACTION

All β-lactam antibiotics interfere with bacterial cell wall synthesis, but the effect on gram-positive and gram-negative bacteria is very different because of the differing nature of their cell walls. In the simplest terms, β-lactam antibiotics interfere with the final transpeptidation reaction that forms the crosslink between adjacent peptidoglycan strands and gives the cell wall its essential rigidity. Various forms of transpeptidase exist depending on whether cell wall structure is engaged in extension of the cylinder of rod-shaped cells, forming the poles of the cell, or separating the two daughter cells during the division process. Realization that β-lactam antibiotics affected all of these processes came from studies that showed concentration-dependent effects on the morphological response of gram-negative bacilli (Greenwood and O'Grady 1973a); by observation that certain β-lactam agents were anomalous in the morphological effects they produced (Greenwood and O'Grady 1973b); and by the demonstration of differential affinity of β-lactam agents for penicillin-binding proteins (PBP) in isolated cell membranes (Spratt 1975). The morphological consequences of binding to various PBPs of *Escherichia coli* are shown in Figure 2. PBPs have been investigated in many gram-positive and gram-negative bacteria. Although their number and molecular size vary considerably, they are always present in multiple forms.

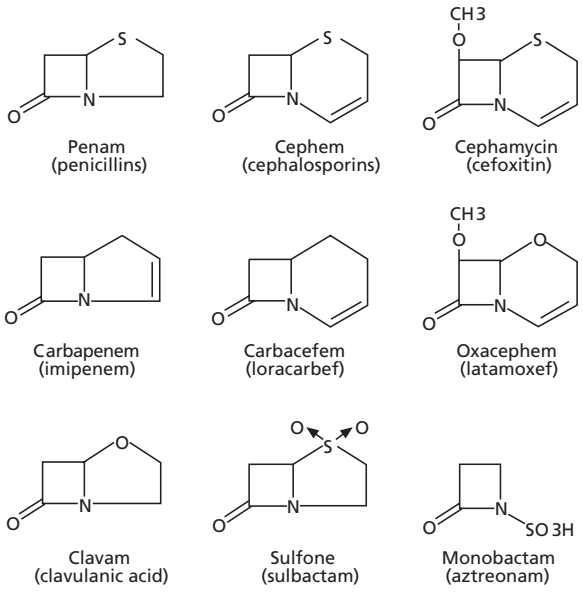

Figure 1 *Core molecular structures of various kinds of β-lactam antibiotics (examples in parentheses). (Redrawn from Greenwood 1995)*

β-Lactam antibiotics are normally bactericidal drugs, but the mechanism of bactericidal activity seems to be different in gram-negative and gram-positive bacteria. In gram-negative rods, cell death can be quantitatively prevented by provision of adequate osmotic protection (Greenwood and O'Grady 1972), so that the mechanism appears to be simple osmotic lysis of bacteria deprived of their normal cell wall. In gram-positive cocci the situation is more complicated: exposure to β-lactam agents causes a loss of lipoteichoic acid from the wall and this seems to remove control from normal autolytic processes that dismantle the peptidoglycan (Tomasz 1979).

Certain strains of gram-positive cocci succumb to the bactericidal effects of penicillin and other β-lactam agents more slowly than usual. Such strains have been dubbed *tolerant* to penicillin (Sabath et al. 1977; Handwerger and Tomasz 1985). Penicillin tolerance may have some relevance in the treatment of bacterial endocarditis or in other situations in which a bactericidal effect is crucial to therapeutic success.

RESISTANCE TO β-LACTAM ANTIBIOTICS

The most common form of resistance to β-lactam agents is caused by enzymes that render the molecules inactive by opening the β-lactam ring. In staphylococci the enzymes involved are inducible exoenzymes that conform to a small number of related types. In contrast, the β-lactamases of gram-negative bacilli vary greatly in their physicochemical characteristics. Indeed, all gram-negative bacilli appear to exhibit some β-lactamase

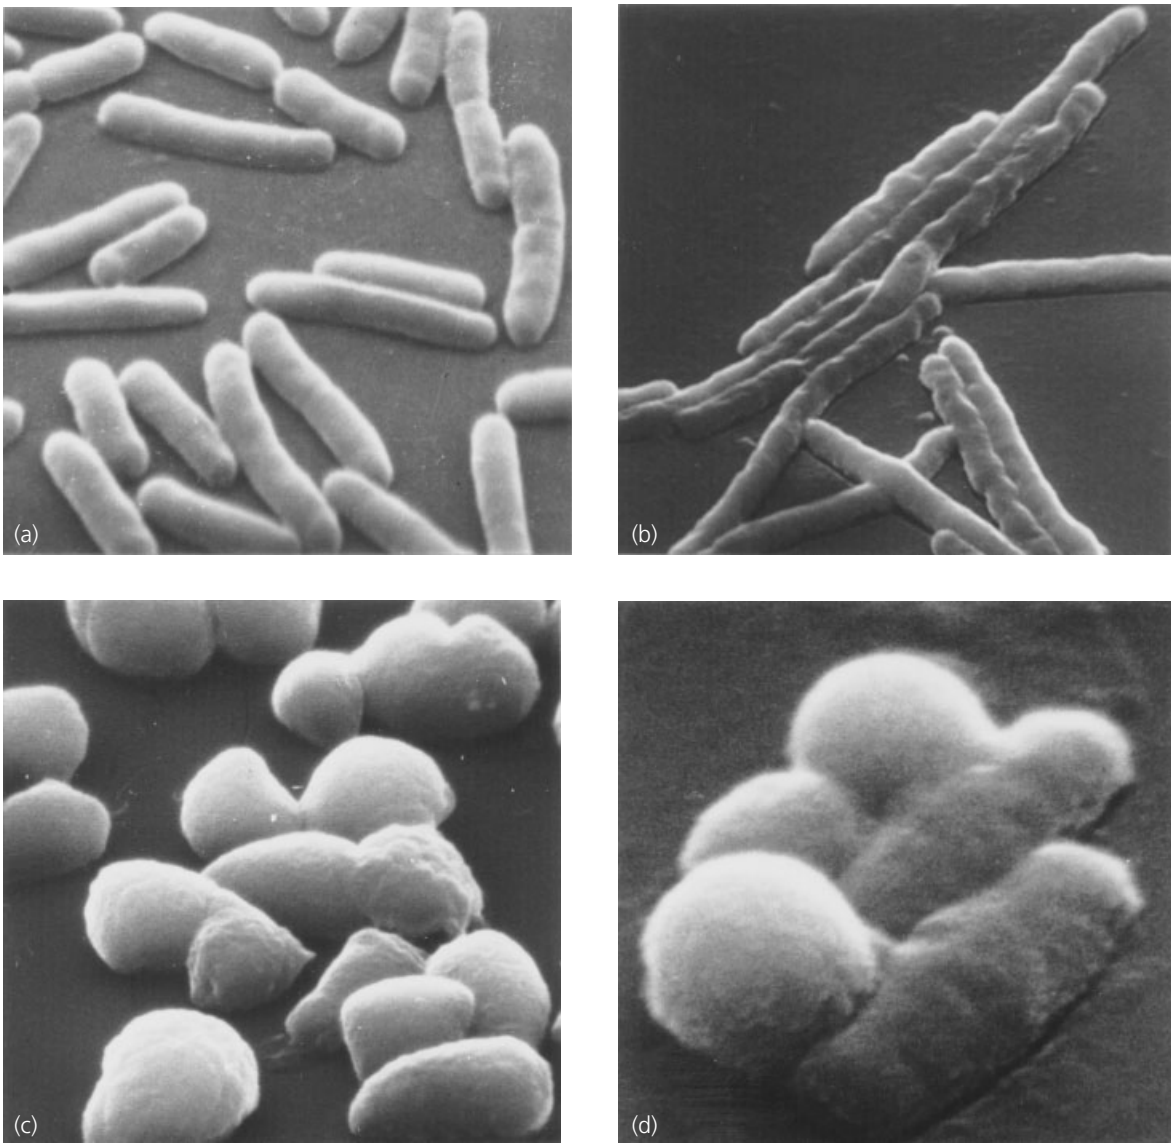

Figure 2 *Morphological effects of β-lactam antibiotics in* Escherichia coli*: **(a)** normal cells (no antibiotic); **(b)** filamentation caused by cephalexin (binding to PBP-3); **(c)** generalized effect on cell wall caused by mecillinam (binding to PBP-2); **(d)** formation of osmotically fragile spheroplasts caused by cephalexin and mecillinam in combination (binding to PBP-2 and PBP-3). Most β-lactam antibiotics, in sufficient concentration, also bind to the PBP-1 complex and cause rapid lysis of susceptible gram-negative bacilli.*

activity as a chromosomally encoded genetic feature. These inherent β-lactamases may be inducible and certain β-lactam antibiotics, notably cefoxitin, are particularly efficient inducers.

There have been various attempts to classify β-lactamases, particularly the many types found in gram-negative rods (Ambler 1980; Richmond and Sykes 1973; Bush 1989). The latest comprehensive classification scheme recognizes four separate molecular types and several functional groupings (Bush et al. 1995).

Although these classification schemes attempt to include all the known types of β-lactamases and are therefore quite complex, the majority of the enzymes that commonly cause problems in clinical isolates of gram-negative bacilli belong to a few related types that share the feature of having serine at the active site and are susceptible to inhibition by clavulanic acid and other β-lactamase inhibitors. Most common of all are the TEM-l and TEM-2 enzymes found widely among enterobacteria and elsewhere, and SHV-l, found predominantly in *Klebsiella pneumoniae*. Many variants of the TEM enzymes have arisen, often by single amino acid substitutions and these may exhibit extended, or idiosyncratic, substrate ranges. Most problematic at present for clinicians are the clavulanic acid-sensitive ESBLs that hydrolyze third and to a lesser extent, fourth generation cephalosporins (Gould 1999) and the clavulanic acid resistant enzymes – the so-called inhibitor-resistant TEM enzymes as they are usually derived from TEM-1 (Chaibi et al. 1999). These enzymes give resistance to

co-amoxiclav and other β-lactamase inhibitors. They may be widespread, but are difficult to test for on a routine basis. TEM-1 itself, and some other β-lactamases, have found their way on to transposons and this has aided their transmission and spread. Bacterial β-lactamases that are able to hydrolyze carbapenems, like imipenem, are still unusual in many countries. They are usually zinc-requiring metalloenzymes that are not susceptible to β-lactamase inhibitors (Payne 1993). They are presently found most commonly in *Acinetobacter* spp., *Aeromonas* spp., and in *Stenotrophomonas maltophilia* and are classified by Bush et al. (1995) as a separate molecular class B (group 3) (see section on Carbapenems).

Resistance to β-lactam antibiotics can arise by means other than β-lactamases. Alterations in porins in the outer membrane of gram-negative bacilli can affect transport of β-lactam antibiotics to their site of action (Nikaido 1985). More importantly, mutations affecting the structure of PBPs can alter their affinity to β-lactam compounds so that inhibitory effects become much less efficient. This, for example, is the mechanism of resistance in methicillin-resistant *Staphylococcus aureus* and in strains of *Streptococcus pneumoniae* that display reduced susceptibility to penicillin (Klugman 1990; Jacoby and Archer 1991).

TOXICITY AND SIDE EFFECTS

Since the β-lactam antibiotics act on a target (bacterial peptidoglycan) that is absent from mammalian cells, they are among the least toxic of all antimicrobial agents. The most troublesome side effect is hypersensitivity, which can range from relatively trivial rashes to life-threatening anaphylactic reactions. Less than 10 percent of patients hypersensitive to penicillins are cross-allergic to cephalosporins (Anne and Resman 1995). Ampicillin and amoxicillin commonly give rise to a maculopapular rash when given to patients with glandular fever; this is not a true hypersensitivity reaction and is not a contraindication to subsequent use of a penicillin. Various other side effects are occasionally encountered. A fuller discussion is provided in the standard texts (Kucers and Bennett 1987; Dollery 1991).

Penicillins

CLASSIFICATION AND SPECTRUM OF ACTIVITY

The various penicillins differ in the nature of the side chain at the C-6 position of the molecule. All except mecillinam (amdinocillin), in which the side chain is joined in an amidino linkage, are acyl derivatives of 6-aminopenicillanic acid (Figure 3).

The original penicillin, benzylpenicillin (penicillin G), has a phenylacetamido group at the 6-amino position. It exhibits exceptionally good activity against the classic pyogenic cocci: staphylococci, streptococci (including pneumococci and enterococci), meningococci, and gonococci. It is also very active against spirochetes, most anaerobes (but not *Bacteroides* spp.), and many gram-positive bacilli. Enterobacteria, *Pseudomonas aeruginosa*, and obligate intracellular bacteria are mostly insensitive.

The chief imperfections of penicillin are: lability to gastric acid, so that it cannot be given orally; an exceptionally short plasma half-life; susceptibility to staphylococcal β-lactamase; and a restricted spectrum of activity. Subsequent developments of penicillin have sought to overcome these shortcomings and presently available compounds can be categorized into several groups with distinctive properties (Table 3).

The long-acting salts of penicillin are poorly soluble depot preparations that are injected intramuscularly and release benzylpenicillin slowly from the injection site. In this way, procaine penicillin can maintain a concentration of penicillin inhibitory to many sensitive organisms for up to 24 h. Benzathine and benethamine penicillin are even less soluble and liberate small amounts of penicillin over several days. An alternative way of sustaining penicillin levels in plasma is by the concurrent administration of probenecid, which competes for the active tubular secretion sites in the kidneys.

Oral derivatives of penicillin, notably phenoxymethylpenicillin (penicillin V), have antibacterial properties very similar to those of benzylpenicillin.

The antistaphylococcal penicillins, of which the isoxazolyl derivatives, oxacillin, cloxacillin, dicloxacillin, and flucloxacillin are most widely used, were designed to overcome the problem of enzymic resistance in staphylococci. They are intrinsically less active than benzylpenicillin and although they retain adequate antistreptococcal activity, their use is largely restricted to infections with penicillinase-producing staphylococci, which now account for more than 90 percent of all isolates in many European countries.

The first successful extension of the spectrum of benzylpenicillin was achieved in 1961 with the β-amino derivative, ampicillin (Rolinson and Stevens 1961). Unlike the parent compound, ampicillin exhibited useful activity against some gram-negative bacilli, including *Haemophilus influenzae*, *Escherichia coli*, *Salmonella* spp., and *Shigella* spp., but not *Klebsiella* spp. or *P. aeruginosa*. Amoxicillin, which is better absorbed when administered orally, followed in 1970. In the meantime, the first penicillin to exhibit (albeit weak) antipseudomonal activity, carbenicillin, the β-carboxy derivative of benzylpenicillin, was described (Knudsen et al. 1967). The thienyl variant of carbenicillin, ticarcillin, and a series of acylureido derivatives of ampicillin (azlocillin, mezlocillin, piperacillin, and apalcillin), all of which display improved antipseudomonal activity, were developed later. None of these compounds is stable to staphylococcal β-lactamase.

Table 3 *Categorization of the most important pencillins in clinical use*

Most important penicillins in clinical use	Availability
Benzylpenicillin (penicillin G)	Available
Long-acting salts (depot preparations)	
Procaine penicillin	Available via import
Benzathine penicillin	Not available in UK
Benethamine penicillin	Not available in UK
Acid-stable (oral) derivatives	
Phenoxymethylpenicillin (penicillin V)	Available
Azidocillin	Not available in UK
Phenethicillin	Not available in UK
Propicillin	Not available in UK
Antistaphylococcal penicillins (stable to staphylococcal β-lactamase)	
Methicillin	Not available in UK
Cloxacillin	Not available in UK
Flucloxacillin	Available
Oxacillin	Not available in UK
Dicloxacillin	Not available in UK
Nafcillin	Not available in UK
Penicillins with activity against enterobacteria	
Ampicillin (and esters)	Available
Amoxycillin	Available
Mecillinam (and ester)	Available as pivmecillinam
Ciclacillin	Not available in UK
Epicillin	Not available in UK
Penicillins that are stable to enterobacterial β-lactamases[a]	
Temocillin	Not available in UK
Penicillins with activity against *Pseudomonas aeruginosa*	
Carbenicillin (and esters)	Not available in UK
Ticarcillin	Available only with clavulanic acid (Timentin)
Azlocillin	Not available in UK
Mezlocillin	Not available in UK
Piperacillin	Available only with tazobactam (Tazocin)
Apalcillin	Not available in UK

a) Ampicillin, amoxicillin, ticarcillin, and piperacillin are also formulated with β-lactamase inhibitors that confer the property of stability to enterobacterial β-lactamases.

Among penicillins that possess an idiosyncratic spectrum of activity that excludes gram-positive cocci and anaerobes are the amidinopenicillins, mecillinam and temocillin, a compound structurally similar to ticarcillin, but rendered stable to enterobacterial β-lactamases by incorporation of a methoxy group on to the β-lactam ring (compare with cefoxitin and other cephamycins). Neither mecillinam nor temocillin has any useful activity against *P. aeruginosa*.

PHARMACOLOGICAL PROPERTIES

Most penicillins are absorbed erratically when given orally, often because of hydrolysis by gastric acid. Phenoxymethylpenicillin and related compounds are acid stable and are used as oral substitutes for benzylpenicillin. Among isoxazolyl penicillins, flucloxacillin achieves the highest plasma concentrations after oral administration. About 30 percent of an oral dose of ampicillin is absorbed, but this can be much improved by esterification of the carboxyl group. These ampicillin esters, talampicillin, pivampicillin, bacampicillin, and lenampicillin, are inactive prodrugs that are de-esterified during passage through the intestinal mucosa with liberation of ampicillin into the bloodstream. Prodrug esters of carbenicillin and mecillinam have also been produced as oral formulations.

Benzylpenicillin and phenoxymethylpenicillin are extremely rapidly excreted, with a plasma half-life of about 30 min. Most other penicillins exhibit elimination half-lives of around 30 min to 1.5 h. Temocillin has an unusually extended half-life of approximately 4–5 h. Protein binding is generally less than 50 percent; the isoxazolylpenicillins are extensively (>90 percent) protein-bound in plasma, but this does not seem to adversely affect their therapeutic activity.

Penicillins do not penetrate the intact blood–brain barrier well, but in the presence of meningeal inflammation concentrations are often sufficient to treat pyogenic

meningitis and benzylpenicillin (meningococcal and pneumococcal meningitis) and ampicillin (*Haemophilus meningitis*) have been widely used for this purpose in the past.

Cephalosporins

CLASSIFICATION AND SPECTRUM OF ACTIVITY

Since they first became available in the mid-1960s, the cephalosporins have been developed more diversely than any other group of antimicrobial agents. They have overlapping properties that defy any rigid classification, but can usefully be divided into six broad classes (Table 4). In the cephalosporins, the extra carbon of the dihydrothiazine ring carries an additional side chain, the nature of which often affects the pharmacokinetic behavior of the molecule and in some cases, the toxicity. Structures of some of the commonly used cephalosporins are shown in Figure 4. As a group, the cephalosporins have certain properties in common: relative stability to staphylococcal β-lactamase; broad spectrum activity that encompasses most enterobacteria, including *Klebsiella* spp.; and lack of activity against enterococci.

Like the penicillins, cephalosporins interfere with bacterial cell wall synthesis through binding to PBPs. Some cephalosporins, notably cephalexin and cephradine, bind almost exclusively to PBP-3, which has the effect of halting division, but not growth, of susceptible gram-negative bacilli. Consequently, these cephalosporins are much more slowly bactericidal than the others and the build up of endotoxin from filamentation may well have deleterious clinical effects (Gould and MacKenzie 1997).

PARENTERAL CEPHALOSPORINS

The first cephalosporins, cephalothin and cephaloridine, modestly expanded the spectrum of ampicillin (e.g. to include *Klebsiella* spp.) and possessed relative stability to staphylococcal β-lactamase. Some later derivatives offered little, if any, improvement, but cephazolin exhibited the unusual characteristic of achieving enhanced concentrations in bile and cephamandole offered partial resistance to some enterobacterial β-lactamases.

The first major improvement in cephalosporins came with the introduction of compounds that displayed stability to a wide range of enterobacterial β-lactamases. One such compound, cefoxitin, is a semisynthetic derivative of a naturally occurring compound in which the β-lactam ring is substituted with a methoxy grouping that confers stability to the structure. Such compounds are called cephamycins; various examples, including cefotetan, cefbuperazone, cefmetazole, and cefminox, are in use around the world. They are unusual among cephalosporins in their activity against *B. fragilis*.

β-Lactamase stability was achieved in a different way by pharmaceutical chemists who found that addition of a methoximino group to the side chain on 7-aminocephalosporanic acid also protected the β-lactam ring from enzymic attack. The first cephalosporin of this type was

cefuroxime, but this was quickly followed by a family of compounds, of which cefotaxime was the forerunner, in which the side chain carried an aminothiazole group, as well as the methoximino substitution. The effect of this was not only to provide β-lactamase stability, but also to much improve the intrinsic antibacterial activity, particularly against enterobacteria. Activity of these compounds against *P. aeruginosa* is, however, poor, but some later derivatives, notably ceftazidime, include this organism in the spectrum. Cefsulodin is unique in exhibiting good antipseudomonal activity, but has little or no useful activity against other organisms. Later developments in the form of cefepime and cefpirome not only provide antipseudomonal activity but some resistance to most ESBLs.

ORAL CEPHALOSPORINS

Few cephalosporins are absorbed when administered by the oral route. Cephalexin was the first of those that are well absorbed; it exhibits modest antibacterial activity against a wide spectrum of gram-positive and gram-negative bacteria, but is slowly bactericidal to enterobacteria because of its preferential affinity for PBP-3 (see above). It has no useful activity against *P. aeruginosa*, *H. influenzae* or *B. fragilis*. Most other oral cephalosporins are structurally similar to cephalexin and not surprisingly, share its limitations. Cefaclor is unusual in displaying useful activity against *H. influenzae* and is especially well absorbed. Attempts have been made to improve the intrinsic activity of oral cephalosporins, or to esterify parenteral compounds to enhance their absorption. Cefixime and ceftibuten display much improved activity against enterobacteria, but have some important weaknesses in their gram-positive spectrum, in particular in their poor activity against staphylococci, enterococci, and some streptococci. Cefpodoxime retains better activity against staphylococci and streptococci. None have useful activity against *P. aeruginosa*. Oral cephalosporins have recently been reclassified (Williams et al. 2001).

PHARMACOLOGICAL PROPERTIES

Cephalosporins, like penicillins, are generally excreted rapidly by the kidneys with elimination half-lives that usually range from 1 to 2 h. The expanded spectrum compound, ceftriaxone, is unusual in that its plasma half-life is about 6–8 h. Cephazolin, cefoperazone, and ceftriaxone are notable in achieving significant concentrations in bile. Those cephalosporins that carry an acetoxymethyl group at C-3 (including cephalothin and cefotaxime) are susceptible to hepatic enzymes which deacetylate the molecule to the corresponding hydroxymethyl derivative. This reduces the inherent antibacterial activity, but there is little evidence that this affects the therapeutic potency. Some other cephalosporins, cephamandole, cefotetan, and cefoperazone among them, have a nitrogen-rich tetramethylthiomethyl substituent at C-3. Compounds with this feature have been implicated in hypoprothrombinemia that is reversible by administration of vitamin K (Lipsky 1988).

Cephalosporins penetrate poorly into cerebrospinal fluid after intravenous administration, but some, notably cefotaxime and ceftriaxone achieve sufficient concentration in the cebrospinal fluid (CSF) in the presence of inflammation for them to be useful for intravenous treatment in bacterial meningitis.

Other β-lactam antibiotics

Several variants on the β-lactam theme other than penams (penicillins) and cephems (cephalosporins and cephamycins) are in therapeutic use (Figure 5).

β-LACTAMASE INHIBITORS

Certain molecules that possess a β-lactam ring, including the naturally occurring antibiotic, clavulanic acid and the penicillanic acid sulfones, sulbactam and tazobactam, are noteworthy not for their intrinsic antibacterial activity, but because they have a high affinity for and stability to, bacterial β-lactamases. These agents are formulated with β-lactamase labile partner compounds to secure their activity against otherwise resistant organisms: clavulanic acid with amoxicillin (co-amoxiclav) or ticarcillin; sulbactam with ampicillin (or with cefoperazone in some countries); tazobactam with piperacillin.

CARBAPENEMS, CARBACEPHEMS, OXACEPHEMS

In the mid-1970s, a potent, broad spectrum β-lactam compound, thienamycin, was found as a naturally occurring product of *Streptomyces cattleya* (Kahan and Kahan 1979). The substance, which was found to possess an unusual carbapenem ring structure, was, unfortunately, inherently unstable, but this was overcome by synthesis of the *N*-formimidoyl derivative, imipenem (Kahan et al. 1983) (see Figure 5). Imipenem has exceptionally good activity against most gram-positive and gram-negative bacteria, including organisms like enterococci, *P. aeruginosa*, and *B. fragilis* that are resistant to most cephalosporins. It is very stable in the presence of bacterial β-lactamases, but by a strange trick of nature it is hydrolyzed by a dehydropeptidase located in the brush border of the mammalian kidney and has to be given with a dehydropeptidase inhibitor, cilastatin (Kahan et al. 1983). A related carbapenem, meropenem, is not susceptible to dehydropeptidase and is therefore administered alone. These compounds are not absorbed when given by mouth and are administered parenterally. Resistance to carbapenems is still uncommon, but they are hydrolyzed by naturally occurring metallo-β-lactamases produced by *S. maltophilia*, *Flavobacterium* sp., *Aeromonas* sp., and *B. fragilis*. Methicillin-resistant staphylococci and penicillin-resistant enterococci are

usually refractory to carbapenems. A new, once daily carbapenem, ertapenem has reduced antipseudomonal activity. Carbapenem resistance in Acinetobacter, Pseudomonas, and some Enterobacteriaceae is becoming an increasing clinical problem. Two types of class B metallo β-lactamase are prevalent: Verona imipenemase (VIM) and IMP. They are now becoming widespread and a VIM-producing *P. aeruginosa* recently spread among 200 patients in Greece (Giakkoupi et al. 2003; Docquier et al. 2003; Jeong et al. 2003). They are very worrying not only because they hydrolyze all β-lactams except the monobactams and are not susceptible to inhibitors, but they can be coded for on integrons.

The possibility of synthesizing carbacephems and oxacephems has also been explored. Two such compounds, loracarbef (a carbacephem) and latamoxef (an oxacephem), have been developed (Figure 5). Loracarbef can be given orally, but does not have the breadth of spectrum or the β-lactamase stability of the carbapenems; its activity and use are similar to those of cefaclor, to which it is related structurally. Latamoxef (also known as moxalactam) is a parenteral compound that exhibits properties similar to those of the expanded spectrum cephalosporins such as cefotaxime, but including *B. fragilis* within the spectrum. It has a methyltetrazole group at C-3 and the associated bleeding problems (see above) have restricted its popularity.

MONOBACTAMS

The idea of developing therapeutically useful compounds in which the β-lactam ring was not fused with another cyclic structure was once thought to be unlikely, if not impossible. Therefore, it came as a surprise when naturally occurring compounds with this feature were described. Only one such compound is in therapeutic use, the semi-synthetic monobactam, aztreonam (Figure 5). In marked contrast to the ultra-broad spectrum of the carbapenems, aztreonam is a narrow spectrum agent, the useful activity of which is restricted to enterobacteria and *P. aeruginosa*. It is administered parenterally. Aztreonam specifically inhibits PBP-3 in *E. coli* and causes filamentation of susceptible gram-negative bacilli, which are killed slowly.

Glycopeptide antibiotics

STRUCTURE AND SPECTRUM OF ACTIVITY

Two glycopeptides, vancomycin and teicoplanin, are in clinical use. A related compound, avoparcin, is used as a growth promoter in animal husbandry. They are complex heterocyclic compounds composed of a heptapeptide substituted with certain sugars, one of which, in teicoplanin, carries a fatty acid chain (Figure 6). The molecule is too large to penetrate the outer membrane of gram-negative bacilli, although some gram-negative anaerobic bacilli are anomalously sensitive, particularly

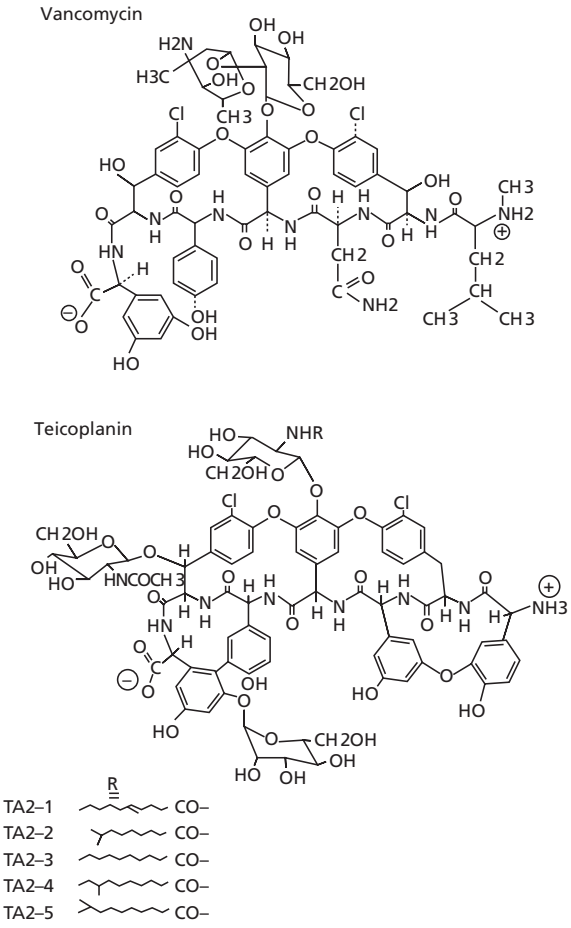

Figure 6 *Structures of the glycopeptide antibiotics, vancomycin and teicoplanin.*

to teicoplanin (Greenwood et al. 1988). Nearly all gram-positive organisms are susceptible, although some genera, including *Lactobacillus*, *Pediococcus*, and *Leuconostoc*, are intrinsically resistant (Ruoff et al. 1988). They are mainly used in serious infection with staphylococci and enterococci that are resistant to other drugs although bactericidal activity is slow. Oral vancomycin has been used in antibiotic-associated colitis in which *Clostridium difficile* is implicated and is still used for refractory cases. New derivatives such as daptomycin are being developed with improved bactericidal activity and daptomycin has already been licensed in some countries.

MODE OF ACTION

Glycopeptides prevent the transfer of peptidoglycan building blocks to the growing cell wall by binding to the acyl-D-alanyl-D-alanine terminus of the pentapeptide side chain (Reynolds 1989).

RESISTANCE

There are many reports of resistance in enterococci (Johnson et al. 1990), and coagulase-negative staphylococci (Sanyal et al. 1993). In enterococci, resistance is

associated with enzymic alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate (Walsh 1993), but other mechanisms are found in coagulase-negative staphylococci. The most common type of resistance in enterococci (*vanA*) is inducible and transferable (Shlaes et al. 1989; Healy and Zervos 1995); high level resistance to both vancomycin and teicoplanin is conferred. Transfer to *S. aureus* has been reported (Noble et al. 1992) and at the time of writing three clinical isolates of this glycopeptide-resistant *S. aureus* have been described (Chang et al. 2003; Public Health Dispatch 2002; Hiramatsu 2004; Kacia, 2004) Heteroresistant strains are also increasingly described with thickened cell walls probably acting as a sump for both vancomycin and teicoplanin (Manuel et al. 2002; MacKenzie et al. 2003). Some vancomycin-resistant isolates of enterococci retain susceptibility to teicoplanin, but *Staphylococcus haemolyticus* isolates are often more resistant to teicoplanin than to vancomycin.

PHARMACOLOGICAL PROPERTIES AND TOXICITY

Vancomycin has to be administered by slow intravenous infusion, since bolus injection is apt to cause 'red-man syndrome' owing to the release of histamine. Teicoplanin is less likely to cause this complication (Sahai et al. 1990). In addition, teicoplanin does not cause tissue necrosis that is associated with intramuscular injection of vancomycin and it can be safely given by this route. The elimination half-life of teicoplanin (approximately 40 h) is much longer than that of vancomycin (approximately 7 h), and it is much more extensively protein bound (90 versus 50 percent). Renal and ototoxicity may be more common with vancomycin, but serum monitoring of both is recommended to ensure efficacious trough levels.

OTHER CELL WALL ACTIVE AGENTS

Bacitracin

This is a cyclic peptide that prevents the dephosphorylation of the lipid carrier molecule that transfers newly formed peptidoglycan across the cell membrane during cell wall synthesis. It is too toxic for systemic use, but is found in several topical preparations. It is mainly active against gram-positive cocci. The exquisite sensitivity of *S. pyogenes* is exploited in a laboratory screening test for that organism.

Cycloserine

This is an analog of D-alanine, which prevents the racemization of L-alanine and the ligation of D-alanyl-D-alanine. It is quite toxic and is now used only as a reserve agent for drug-resistant *M. tuberculosis*, although it used to be prescribed for prophylaxis of recurrent urinary tract infections.

Fosfomycin

Fosfomycin (epoxypropylphosphonic acid) is a broad spectrum antibiotic that blocks the formation of *N*-acetylmuramic acid from *N*-acetylglucosamine by inhibition of pyruvyltransferase. In vitro activity against *E. coli* and some other gram-negative rods is potentiated by glucose-6-phosphate, which induces a hexose phosphate transport pathway. The sodium salt is used for parenteral administration; for oral use, the earlier calcium salt has been superseded by the much more soluble trometamol formulation, which is particularly suitable for the treatment of urinary tract infection (Reeves 1994). Resistance to fosfomycin emerges readily in vitro, but the drug has been extensively used in some countries without apparent problem. Plasmid-mediated resistance has been reported (Suárez and Mendoza 1991), but is as yet uncommon. A somewhat similar phosphonic acid derivative, fosmidomycin, is available in Japan.

Ethambutol, isoniazid, and pyrazinamide

These are agents used specifically in mycobacterial disease; they have no useful activity against other bacteria. Although the mode of action has not been definitely established, it is likely that they act on the mycobacterial cell wall, which is unusual in its composition. Isoniazid is most active against *M. tuberculosis* against which it exerts bactericidal activity. It is well absorbed when given orally and is eliminated in the urine, largely in an acetylated form. In persons with a genetically determined ability to acetylate the drug rapidly, excretion is hastened and plasma concentrations correspondingly low. Unfortunately, resistance is an increasing problem (Pablos-Mendez et al. 1998; Warburton et al. 1993). Pyrazinamide is also mycobactericidal, but only at an acid pH and after intracellular conversion by a bacterial amidase to pyrazinoic acid (Mitchison 1992). Ethambutol, by contrast, is predominantly mycobacteristatic, but it has a wider spectrum of activity within the mycobacteria, including activity against organisms of the *Mycobacterium avium* complex.

INHIBITORS OF BACTERIAL PROTEIN SYNTHESIS

Many of the naturally occurring antibiotic families that were discovered by mass screening of soil samples in the 1940s and 1950s turned out to achieve their antibacterial effect by interfering with various stages of the process of protein synthesis. Some, but not all, owe their selective

toxicity to the difference in structure between bacterial and mammalian ribosomes.

Aminoglycosides

STRUCTURE AND SPECTRUM OF ACTIVITY

Aminoglycosides are complex heterocyclic compounds that usually possess an aminocyclitol group in addition to one or more amino sugars. Spectinomycin is unusual in being a pure aminocyclitol and has properties, including predominantly bacteristatic activity, that separate it from the aminoglycosides proper. It is used only as a reserve agent in gonorrhea. The remaining aminoglycosides can be divided into two main types depending on the structure of the aminocyclitol ring: those (of which streptomycin and dihydrostreptomycin are the only surviving examples) in which the aminocyclitol is streptidine; and those in which the aminocyclitol moiety is deoxystreptamine. The deoxystreptamine-containing aminoglycosides can, in their turn, be divided into neomycin derivatives, kanamycin derivatives, and gentamicin derivatives (Figure 7).

The neomycins (including framycetin; neomycin B), are mainly used in topical preparations because of their toxicity, but one member of the group, paromomycin, is more conspicuous for its activity against the protozoa *Entamoeba histolytica* and *Leishmania* spp. Most of the remaining aminoglycosides in common therapeutic use, including gentamicin, tobramycin (deoxykanamycin B), netilmicin and the semisynthetic antibiotic, amikacin, share a common spectrum of activity that encompasses staphylococci and enterobacteria, but excludes streptococci, enterococci, anaerobes, and intracellular bacteria. Certain aminoglycosides exhibit activity against *M. tuberculosis* (streptomycin, kanamycin, and amikacin) or against *P. aeruginosa* (gentamicin, tobramycin, netilmicin, amikacin). Members of this last group have been widely used in the management of serious infection, often in combination with a β-lactam agent with which they may interact synergically. Bactericidal synergy with penicillin is also exploited in the therapy of streptococcal and enterococcal endocarditis.

MODE OF ACTION

Aminoglycosides bind to bacterial ribosomes. A single amino acid change in a protein of the 30S ribosomal subunit renders the cells completely resistant to streptomycin, but not to deoxystreptamine-containing aminoglycosides, which bind to both subunits. The mechanism of action is uncertain. Binding induces misreading of messenger RNA so that defective proteins are produced, but it is likely that aminoglycosides also interfere with the formation of functional initiation complexes. Neither of these mechanisms satisfactorily explains the potent bactericidal activity of these compounds and this may follow from membrane-related effects (Davis 1988).

RESISTANCE

Aminoglycosides are taken up by bacterial cells by an active transport process that involves respiratory processes. The absence of such a transport mechanism in anaerobes, streptococci, and enterococci accounts for the relative resistance of these organisms.

Alterations in permeability characteristics of sensitive bacteria may lead to relative resistance to aminoglycosides, and such bacteria are usually resistant to all members of the group. However, acquired resistance in otherwise sensitive species is most commonly due to the production of enzymes that adenylate or phosphorylate hydroxyl groups on the aminoglycoside molecule, or acetylate exposed amino groups. Since these antibiotics vary in the availability of vulnerable groupings on the molecule, they exhibit variable susceptibility to the many aminoglycoside-modifying enzymes that have been described. Some examples are shown in Table 5.

PHARMACOLOGICAL PROPERTIES

Aminoglycosides are very poorly absorbed by the oral route and are administered by intramuscular injection or intravenous infusion. They do not penetrate into cells or cross the blood–brain barrier to enter the cerebrospinal fluid. They are excreted almost entirely in the urine via the glomerular filtrate with an elimination half-life of about 2–4 h. Protein binding is generally low (<25 percent).

TOXICITY AND SIDE EFFECTS

All members of this antibiotic family are nephrotoxic and ototoxic, but they vary in their propensity to cause these adverse effects. For example, gentamicin and tobramycin are less likely to cause vestibular toxicity than is streptomycin, but are somewhat more likely to cause renal damage. Because of the risk of toxicity, it is common practice to assay aminoglycoside levels after intramuscular injection or intravenous infusion ('peak' level) and immediately before the next dose ('trough' level). If single large daily doses of aminoglycosides are used, as is increasingly advocated (Levison 1992), peak levels become difficult to interpret, but trough levels still need to be monitored (Nicolau et al. 1995).

Chloramphenicol

STRUCTURE AND SPECTRUM OF ACTIVITY

Chloramphenicol is a relatively simple antibiotic (Figure 8) that is nowadays synthesized rather than being obtained by fermentation from the producer organism. Modification of the molecule has not been very productive, although thiamphenicol, in which a sulphomethyl substituent replaces the nitro group, is available in some countries. The figures in parentheses indicate the sites of modification of exposed amino or hydroxyl groups according to the international numbering system for the heterocyclic ring structure of the aminoglycosides. Bifunctional enzymes that act at more than one site have two such numbers. Roman numerals indicate different forms of the enzyme acting at that site.

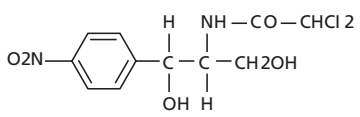
such as florphenicol, have also been made, but are not used in human medicine.

The spectrum is very broad and includes intracellular pathogens, such as chlamydiae and rickettsiae, as well as most conventional gram-positive and gram-negative bacteria. *P. aeruginosa* and *M. tuberculosis* are usually resistant.

MODE OF ACTION

Chloramphenicol inhibits the enzyme peptidyl-transferase which links new amino acids from aminoacyl transfer RNA to the growing peptide chain. It does not bind to mammalian ribosomes except, perhaps, those within mitochondria.

Chloramphenicol



Thiamphenicol

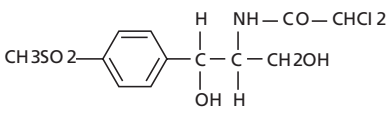


Figure 8 *Structures of chloramphenicol and thiamphenicol.*

RESISTANCE

Target site alterations and reduction in drug uptake have been described, but the most common form of resistance is due to the production of chloramphenicol acetyltransferases. These enzymes acetylate the C-3 hydroxyl group preferentially, but also attack the C-1 hydroxyl; interest in the fluorinated derivatives centers on their resistance to these enzymes. Inactivation of chloramphenicol by a nitroreductase has also been described in *B. fragilis* (Tally and Malamy 1984).

PHARMACOLOGICAL PROPERTIES

Because chloramphenicol is poorly soluble and tastes very bitter, prodrugs are used in therapy: water-soluble chloramphenicol succinate is used for injection and the more palatable chloramphenicol palmitate or stearate for oral administration. These salts release chloramphenicol in the body, but are themselves inactive and unsuitable for laboratory tests. The oral route of administration is very efficient and is generally preferred. The drug is well distributed, with excellent penetration into the cerebrospinal fluid. It is excreted into urine, largely as inactive glucuronide conjugates, with a half-life of about 2–5 h in adults. Plasma protein binding is approximately 50 percent.

TOXICITY AND SIDE EFFECTS

The popularity of this excellent antibiotic suffered a severe setback when it was realized that it occasionally caused an irreversible aplastic anemia. The overall

incidence of this lethal side effect is about 1 in 40 000 courses of therapy, but there may be a genetic component that makes it more likely in some patients. There is concern that sufficient chloramphenicol may be absorbed systemically after topical use, e.g. in eye ointments, for aplastic anemia to be a hazard (Doona and Walsh 1995), but the degree of risk is disputed (Mulla et al. 1995). Thiamphenicol appears to be free of this side effect, but is more likely to cause reversible depression of the bone marrow.

Young infants have a limited capacity to conjugate and excrete chloramphenicol; accumulation of the drug may lead to 'gray baby' syndrome, with circulatory collapse. For this reason chloramphenicol levels should be assayed if the drug is used in neonatal meningitis or other life-threatening conditions in young infants.

Tetracyclines

STRUCTURE AND SPECTRUM OF ACTIVITY

The tetracyclines are a closely related group of naturally occurring and semisynthetic antibiotics that differ according to the nature of chemical substituents on the basic tetracyclic skeleton (Figure 9). They are distinguished more for differences in pharmacokinetic behavior than for variations in antimicrobial activity. The spectrum of activity is broad. They have been widely and successfully used in many types of infection including those in which chlamydiae, rickettsiae, and mycoplasmas are involved. They have some antiprotozoal activity and are sometimes used in drug-resistant malaria.

Minocycline	—H	— N(CH3)(CH3)	H, H
Doxycycline	—OH	— H	CH3, H

Figure 9 *Structures of the most important tetracyclines.*

MODE OF ACTION

Tetracyclines enter bacterial cells by an active uptake process. They bind to the 30S ribosomal subunit and prevent access of aminoacyl transfer RNA to the acceptor site by a mechanism that has not been fully elucidated (Chopra et al. 1992). Mammalian cells do not concentrate tetracyclines in the way that bacteria do and the ribosomes (other than mitochondrial ribosomes) are relatively insusceptible.

RESISTANCE

The emergence of resistance in gram-positive and gram-negative bacteria has seriously undermined the value of tetracyclines although most epidemic strains of MRSA in the UK retain susceptibility. Resistance is generally plasmid mediated and is commonly found on transposons. Several mechanisms of resistance have been described, but the most prevalent appears to be due to production of a novel cytoplasmic membrane protein that mediates active efflux of the drug so that inhibitory levels are not maintained within the cell (Chopra et al. 1992; Speer et al. 1992).

Resistance usually affects all tetracyclines equally, although minocycline may retain activity against some strains. Efforts have been made to devise tetracyclines that overcome resistance mechanisms. Several candidate molecules have been described, including the glycylcyclines which are under investigation (Tally et al. 1995). One of these, tigecycline is in an advanced stage of development (Milatovic et al. 2003). It is a derivative of minocycline and offers useful activity for problem multiresistant gram-positive cocci such as MRSA, penicillin resistant pneumonia (PRP), and vancomycin-resistant enterococci (VRE).

PHARMACOLOGICAL PROPERTIES

The tetracyclines are usually given orally, but since they form nonabsorbable chelates with divalent cations, administration with milk or other food may interfere with absorption. Doxycycline and minocycline are among the best absorbed; these compounds also have a longer plasma half-life (approximately 16–18 h) than other congeners (generally approximately 6–12 h), but are more extensively (minocycline 75 percent; doxycycline 90 percent) protein bound. They penetrate well into tissues, but not into cerebrospinal fluid. They are excreted by glomerular filtration into the urine and into feces via the bile.

TOXICITY AND SIDE EFFECTS

Diarrhea and other forms of gastrointestinal intolerance are common. Renal failure may occur in patients who already have impaired renal function, but doxycycline, which is predominantly excreted by the hepatobiliary route, may be safely given to such patients. Since tetracyclines are yellow compounds that chelate calcium, the

pigment is deposited in growing bone and teeth. For this reason, tetracyclines should not be given to young children when the dentition is being formed as permanent discoloration of teeth may occur.

Macrolides

STRUCTURE AND SPECTRUM OF ACTIVITY

The macrolides are a family of related compounds that feature a large macrocyclic lactone structure substituted with various unusual sugars (Figure 10). Erythromycin (the oldest and best known member of the group), oleandomycin, clarithromycin (6-*O*-methyl erythromycin), dirithromycin, and roxithromycin have a 14-membered lactone ring. Some others that are used in various parts of the world, including spiramycin, josamycin, midecamycin, kitasamycin, and rokitamycin, possess a 16-membered lactone structure. In azithromycin, the 14-membered structure of erythromycin has been expanded by insertion of a methyl-substituted nitrogen atom; the 15-membered ring thus produced is sometimes referred to as an azalide structure.

Erythromycin and other macrolides are unable to penetrate easily through the outer membrane of enteric gram-negative bacilli, although they exhibit a variable degree of activity against *H. influenzae*, *Legionella pneumophila*, and *Campylobacter jejuni*. They exhibit good activity against staphylococci and streptococci and useful activity against *Mycoplasma pneumoniae* (but not *M. hominis*) and some environmental mycobacteria. Chlamydiae are susceptible and azithromycin is effective in

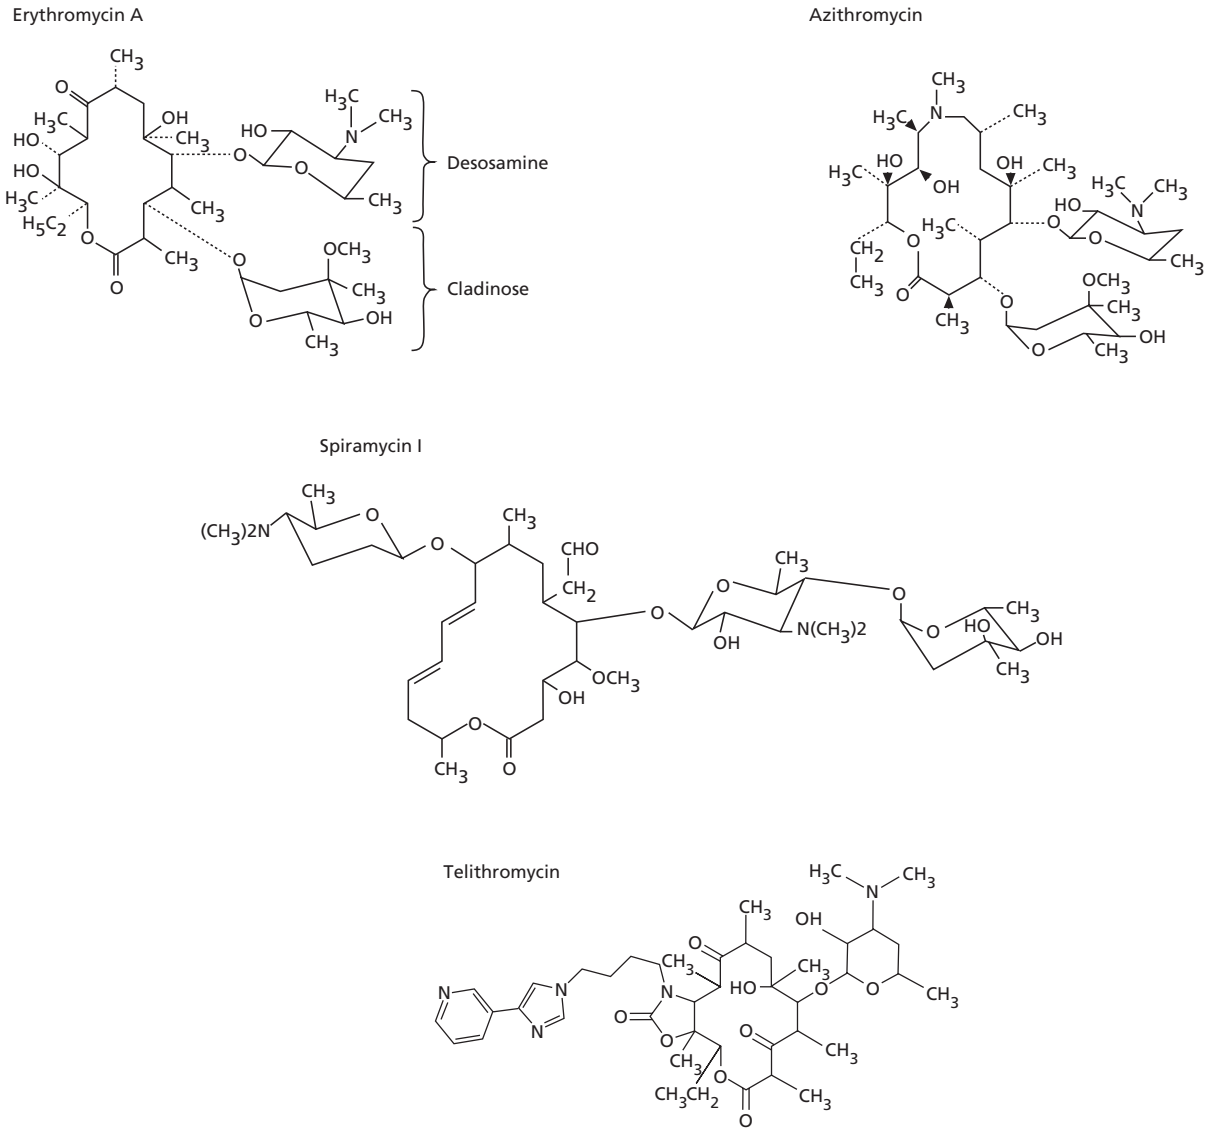

Figure 10 *Structures of erythromycin A (a l4-membered macrolide); azithromycin (a 15-membered macrolide and an azalide); spiramycin I (a 16-membered macrolide); and telithromycin.*

the single-dose treatment of genital infections (Martin et al. 1992; Stamm et al. 1995) and trachoma (Bailey et al. 1993). Spiramycin has been successfully used in toxoplasmosis and clarithromycin has a place in regimens for the eradication of *Helicobacter pylori*. The ketolide derivatives have undergone development recently and one of them, telithromycin is being used clinically. Its spectrum of activity and structure is very similar to clarithromycin, although it is bactericidal rather than static, like traditional macrolides (Fogarty et al. 2003).

MODE OF ACTION

Macrolides bind to 50S ribosomal subunits in bacteria and interfere with the translocation process during synthesis of polypeptides, probably by causing dissociation of peptidyl transfer RNA from the ribosome (Mazzei et al. 1993).

RESISTANCE

Resistance to macrolides is quite commonly encountered in staphylococci and streptococci but the prevalence varies considerably from country to country. Resistance may arise from alterations in ribosomal proteins. It is, though, more commonly due to an inducible, plasmid-mediated enzyme that methylates an adenine residue in ribosomal RNA (Weisblum 1995a) or alternatively, due to active efflux (Alós et al. 2003; Low 2002). The former is due to the *erm (B)* gene which exhibits the MLS_B phenotype, the latter to the *mef (A)* gene which exhibits the M phenotype. This latter mechanism tends to give lower levels of resistance although probably still clinically significant (Lonks et al. 2002). Both efflux and the methylase gene are widespread, but geographical distribution varies. Only 14- and 15-membered ring macrolides are susceptible to efflux but methylase also confers resistance to lincosamides and streptogramins when constituitively expressed although these antibiotics do not act as inducers, so the organisms appear sensitive in laboratory tests, unless erythromycin is also present to induce the enzyme. Variants readily emerge on exposure to lincosamides or streptogramins exhibiting constitutive resistance (Weisblum 1995b). It has been suggested that the newer long-acting macrolides are responsible for recent increases in resistance because of their lack of cidal activity and their prolonged but low tissue levels (Baquero et al. 2002). The ketolides, so far, retain activity against the great majority of erythromycin-resistant streptococci, although not MRSA (Fogarty et al. 2003).

PHARMACOLOGICAL PROPERTIES

Macrolides are mostly irregularly absorbed when given orally; in the case of erythromycin this is because it is unstable at gastric pH. Newer macrolides, such as azithromycin and clarithromycin, are more acid stable and their oral absorption is consequently much improved. Oral formulations of erythromycin are either coated to avoid destruction in the stomach, or are presented as prodrug salts or esters (estolate, stearate, or ethylsuccinate). The lactobionate or gluceptate salts are used for parenteral administration.

All these drugs are well distributed in the body, but azithromycin and clarithromycin are said to achieve particularly good intracellular levels, especially in the lung (Honeybourne and Baldwin 1992). Penetration into cerebrospinal fluid is poor. They are extensively metabolized (except azithromycin) and excreted largely by the hepatobiliary route. The plasma half-life is variable and may be dose-dependent. Azithromycin is unusual in that it has a much extended terminal half-life. The poor serum levels, particularly of azithromycin, make it less desirable for the treatment of bacteremic pneumococcal pnemonia (Lonks et al. 2002).

TOXICITY AND SIDE EFFECTS

Nausea and other gastrointestinal side effects are common, but newer derivatives, including azithromycin and clarithromycin, are better tolerated. Cholestatic jaundice is described as an uncommon complication, particularly with erythromycin formulations. The immunomodulatory and anti-inflammatory properties of macrolides are being investigated in cystic fibrosis and there is good evidence of their benefit in diffuse panbronchiolitis (Krishnan et al. 2002).

Lincosamides

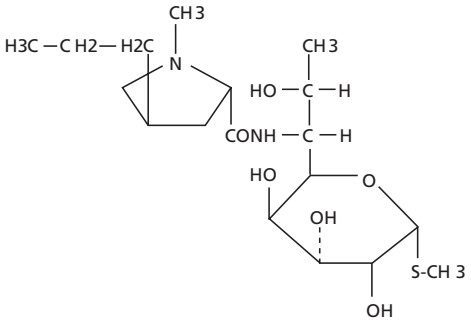
STRUCTURE AND SPECTRUM OF ACTIVITY

The original lincosamide antibiotic, lincomycin, has been largely superseded by the 7-deoxy-7-chloro derivative, clindamycin (Figure 11), which is more active and better absorbed by the oral route. The most potent activity is against staphylococci, streptococci, and anaerobes, including *B. fragilis*. Enterobacteria and *P. aeruginosa* are resistant. Activity against *Propionibacterium acnes* and corynebacteria has led to the use of clindamycin in acne, but its success in this condition may be equally due to the anti-inflammatory and antiphagocytic activity that it is known to possess (Oleske and Phillips 1983) or to effects on skin lipids. Clindamycin possesses some antiprotozoal activity and has been used in malaria and toxoplasmosis.

MODE OF ACTION

The mechanism of action of lincosamides is not known for certain. Early work suggested that these drugs, like chloramphenicol, interfere with the peptidyltransferase reaction (Weisblum and Davies 1968), but later evidence pointed to effects on peptide chain initiation (Pestka 1971; Reusser 1975). Although the structure of lincosamides is completely different from that of macrolides,

Lincomycin



Clindamycin

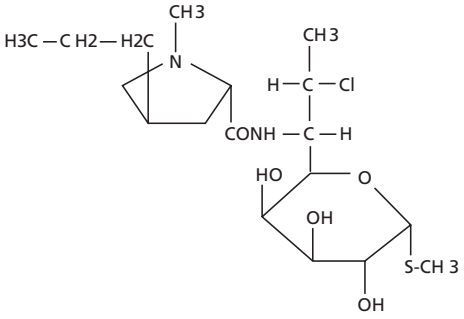


Figure 11 *Structures of the lincosamides, lincomycin and clindamycin.*

the site of action appears to be similar since methylation of an adenine residue in ribosomal RNA confers resistance to both types of antibiotic.

RESISTANCE

As well as resistance caused by ribosomal methylase, described above, resistance may also arise by enzymic modification by nucleotidylation (Russell and Chopra 1996). Resistance emerges readily and is common among methicillin-resistant *S. aureus* (Maple et al. 1989).

PHARMACOLOGICAL PROPERTIES

Like chloramphenicol, clindamycin is poorly soluble and very bitter, so that it has to be administered as inactive prodrugs, clindamycin palmitate (for oral use) and clindamycin phosphate (for injection). It is well absorbed when given orally and after hydrolysis, achieves good concentrations in tissues, but not in the cerebrospinal fluid. It is metabolized in the liver and excreted mainly in bile with a half-life of about 2–3 h. Plasma protein binding is 94 percent.

TOXICITY AND SIDE EFFECTS

Rashes and other occasional adverse events have been overshadowed by the reputation of clindamycin for inducing diarrhea associated with *C. difficile* toxins, which may progress to a life-threatening pseudomembraneous colitis. Other antibiotics, including β-lactam agents, have been implicated in this side effect, but it seems to be more common with clindamycin (Tedesco et al. 1974; Aronsson et al. 1984).

Fusidic acid

STRUCTURE AND SPECTRUM OF ACTIVITY

Fusidic acid is an antibiotic with a steroid-like structure (Figure 12) that does not possess steroid-like activity.
It exhibits modest activity against streptococci, gram-positive and gram-negative anaerobes, *Nocardia asteroides*, and *M. tuberculosis* and good activity against *Corynebacterium diphtheriae*, but its place in therapy hinges on its excellent activity against staphylococci (Greenwood 1988; Verbist 1990). Various interactions with penicillins (synergy, antagonism, and indifference) have been described (O'Grady and Greenwood 1973). Activity against the protozoa, *Giardia lamblia* (Farthing and Inge 1986) and *Plasmodium falciparum* (Black et al. 1985), have been reported. Enterobacteria and pseudomonads are resistant.

MODE OF ACTION

Unlike other inhibitors of bacterial protein synthesis, fusidic acid does not bind directly to the ribosome. It forms a stable complex with guanosine triphosphate and 'factor G', an elongation factor involved in the translocation of the growing peptide chain (Cundliffe 1972).

RESISTANCE

Resistance may be plasmid mediated, but is more commonly due to chromosomal mutation resulting in alteration in the factor G target. This type of resistance emerges readily in vitro, but the general prevalence of resistance in staphylococci has remained low (Shanson 1990). This may have been helped by the fact that

Fusidic acid

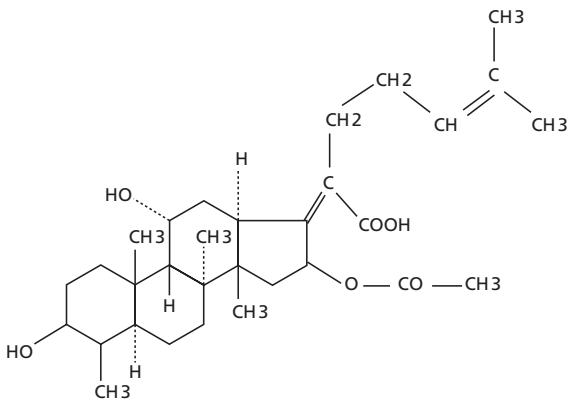

Figure 12 *Structure of fusidic acid.*

fusidic acid is usually given in combination (often with a penicillin) to avoid the emergence of resistance during therapy, but topical preparations are normally given alone and there have been recent concerns that increased resistance has been due to such topical use (Mason et al. 2003).

PHARMACOLOGICAL PROPERTIES

Fusidic acid is very well absorbed by the oral route and penetrates well into tissue, including bone. It is excreted via the bile, mostly as inactive metabolites, with a half-life of about 9 h (Reeves 1987; MacGowan et al. 1989). More than 95 percent is bound to plasma protein.

TOXICITY AND SIDE EFFECTS

A small proportion of patients develop transient jaundice by interference with the metabolism and excretion of bilirubin. It is more common in patients receiving intravenous fusidic acid (Humble et al. 1980). Mild gastrointestinal upsets and rashes are occasionally experienced.

Other inhibitors of bacterial protein synthesis

STREPTOGRAMINS

The streptogramins are a family of antibiotics that consist of two synergically interacting macrolactone components: a polyunsaturated peptolide and a hexadepsipeptide. The bactericidal synergy that results from the combined action of the two components of streptogramins is thought to arise through binding to adjacent sites on the bacterial ribosome (Aumercier et al. 1992). The best known members of the group are pristinamycin and virginiamycin, which are used as antistaphylococcal agents in animal husbandry and, in some countries, in human medicine. Lack of aqueous solubility and poor oral absorption have limited their value, but water-soluble derivatives of the two components of pristinamycin (known, respectively, as quinupristin and dalfopristin) have been synthesized to allow parenteral administration and are now available as a combination for parenteral administration in many countries (Barrière et al. 1992; Etienne et al. 1992) (Figure 13).

Their broad gram-positive spectrum and bactericidal activity ensures their increasing use in difficult to treat cases due to MRSA, PRP, and VRE, but it is only static against *E. faecium* and *E. faecalis* is innately resistant (Eliopoulos 2003). Synergy with glycopeptides and other drugs has been demonstrated (Moyenuddin et al. 2003). Macrolide–lincosamide resistance associated with an adenine methylase also extends to streptogramins (see section on macrolide resistance).

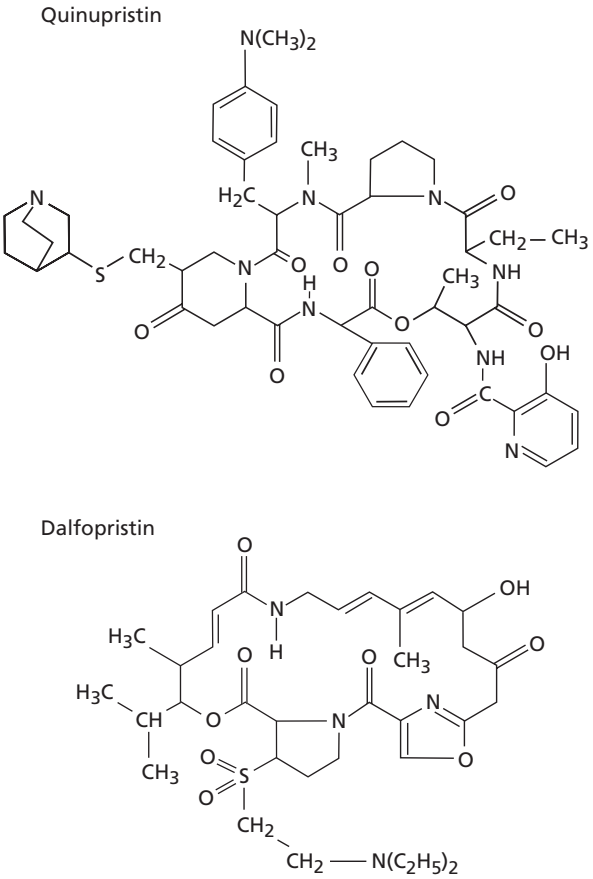

Figure 13 *Structure of quinupristin and dalfopristin.*

OXAZOLIDINONES

This group of drugs are being developed in response to clinical need for new agents active against MRSA and other multiresistant gram-positive organisms. Currently only one, linezolid, has been released for general clinical use (Clemett and Markham 2000). These drugs are the first genuinely new class of antibiotics to be successfully developed for many years (Figure 14). They act at the messenger RNA level where they are thought to interfere with protein synthesis.

As a result of this there is an interesting association with macrolide resistance. To date, when linezolid resistance develops in MRSA it is associated with a reversion to macrolide susceptibility. Development of resistance is, however, very rare to date and associated with long courses of therapy (Wilson et al. 2003; Boo et al. 2003).

Although linezolid is not bactericidal against MRSA, several preliminary reports of randomized studies show it to be more efficacious than glycopeptide monotherapy for serious MRSA infections such as bacteraemia and ventilatory association pneumonia (Cepeda et al. 2004). It seems well tolerated in general, although long-term use has been associated with marrow suppression and neuropathology. There are also some dietary restrictions to be adhered to when it is used because of its inhibitor

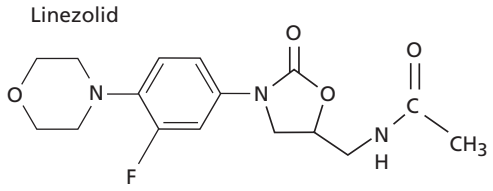

Figure 14 *Structure of linezolid.*

of monoamine oxidase. Currently linezolid should be reserved for serious MRSA infections where conventional therapy has failed. Caution should be exerted in its long-term use, although its excellent bioavailibility makes it a good candidate for oral switch. In vitro studies suggest it is often additive or synergistic in combination with other anti-MRSA drugs and consideration should be given to combinations, e.g. with rifampin in high inoculum or recalcitrant infections (Grohs et al. 2003; Cédrick et al. 2003).

MUPIROCIN

Mupirocin is a naturally occurring antibiotic product of *Pseudomonas fluorescens*. It was formerly known as pseudomonic acid. The structure (Figure 15) is unrelated to other antibiotics and consists of 'monic acid', the distal portion of which is a structural analog of isoleucine and a short fatty acid (nonanoic acid). The useful activity is restricted to gram-positive cocci, in which it presumably halts protein synthesis by binding to isoleucyl transfer RNA synthetase as it does in *E. coli* (Hughes and Mellows 1980).

Although it displays low toxicity, systemic use of mupirocin is precluded by the fact that it is rapidly inactivated in the body. Consequently, it is used only for topical application in skin infections and to eradicate staphylococci from nasal carriers. For the latter purpose, which has been of particular value in carriers of methicillin-resistant *S. aureus*, a paraffin-based formulation is used, rather than the polyethylene glycol-based ointment applied to skin.

INHIBITORS OF BACTERIAL NUCLEIC ACID SYNTHESIS

A surprising number of antibacterial agents achieve their effect by interacting with bacterial DNA in various ways. Sulfonamides and trimethoprim have an indirect effect on other cellular functions, as well as DNA, through their effect on folic acid synthesis, but for convenience are dealt with under this heading.

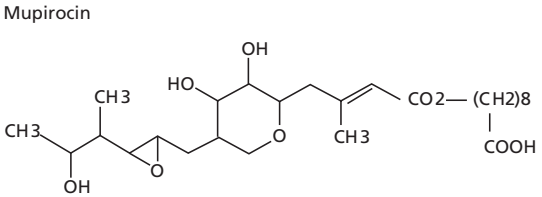

Figure 15 *Structure of mupirocin.*

Sulfonamides

STRUCTURE AND SPECTRUM OF ACTIVITY

The sulfonamides are a large family of compounds, all of which are derived from the original hydrolysis product of Prontosil red, sulfanilamide. They differ in the nature of the substitution on the amino group of the sulfonamide (SO_2NH_2) moiety (Figure 16). The antileprosy drug, dapsone (diaminodiphenylsulphone) and the tuberculostatic *p*-aminosalicylic acid are related substances that are thought to act in a similar way.

They are broad spectrum, predominantly bacteristatic compounds that have a relatively slow effect in halting bacterial growth. Activity in vitro is profoundly affected by the composition of the culture medium, because of the possible presence of interfering substances such as

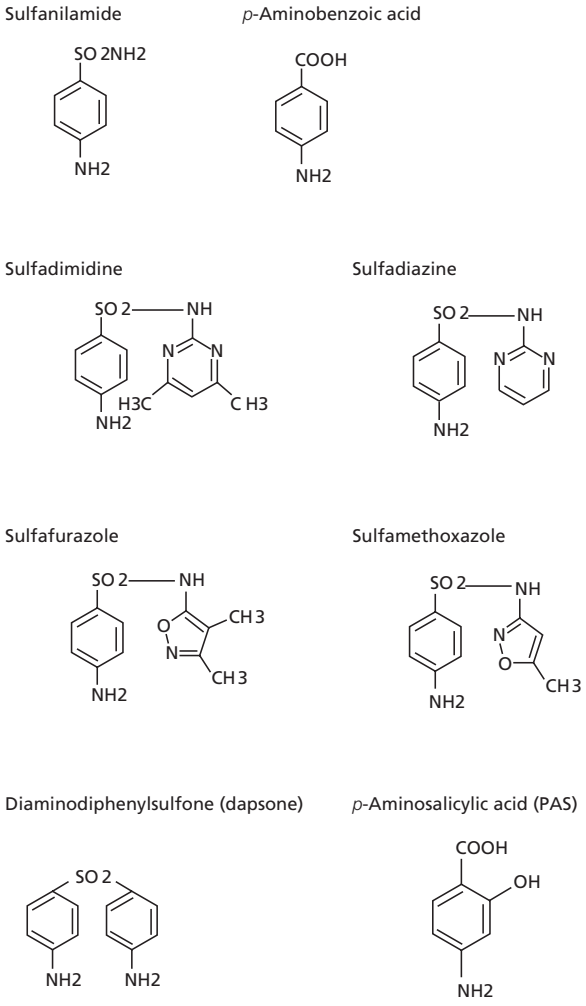

Figure 16 *Structures of some sulfonamides and related compounds.*

folic acid, *p*-aminobenzoic acid, and thymidine. Lysed horse blood, which contains the enzyme thymidine phosphorylase, is commonly added to remove thymidine (Waterworth 1978) and media recommended for sensitivity testing have low levels of this and other sulfonamide antagonists (Report 1991).

MODE OF ACTION

Sulfonamides are analogs of *p*-aminobenzoic acid. They inhibit folic acid synthesis by competitive inhibition of dihydropteroic acid synthetase, the enzyme that brings about the condensation of dihydropteridine with *p*-aminobenzoic acid in the early stage of folate production. Since folic acid is conserved in bacterial cells, the inhibitory effects of sulfonamides become apparent only after several generations of growth when the folate pool has been progressively diluted to below a functional level by distribution to the bacterial progeny.

The selective toxicity of sulfonamides arises because bacteria synthesize folic acid de novo, whereas humans absorb the vitamin preformed. Since they block an early stage of the same metabolic pathway as diaminopyrimidines, sulfonamides interact synergically with those compounds.

RESISTANCE

Resistance to sulfonamides occurs readily and was soon apparent in the early life of these agents. There is complete crossresistance among different members of this drug class. Resistance is commonly plasmid mediated and is usually caused by alterations in dihydropteroate synthetase, leading to less efficient binding of sulfonamides, or bypass of the effects of the agents by a duplicate, insensitive version of the enzyme (Huovinen et al. 1995). Chromosomal resistance due to hyperproduction of *p*-aminobenzoic acid is also recognized (Towner 1992a).

PHARMACOLOGICAL PROPERTIES

Differences in pharmacokinetic behavior are the chief distinguishing characteristics of the various members of the sulfonamide family. In particular, they vary in oral absorption (e.g. phthalylsulfathiazole is very poorly absorbed), protein binding (e.g. sulfadimidine and sulfadoxine are more than 90 percent protein bound) and, above all, plasma half-life, which can vary from about 2.5 h (sulfamethizole) to >100 h (sulfadoxine). The most commonly used sulfonamides, sulfadiazine and sulfamethoxazole (as co-trimoxazole) are well absorbed by the oral route and are excreted into urine, partly as inactive *N*-acetylated metabolites and glucuronide conjugates, with a half-life of about 8–10 h. They are well distributed and penetrate into the cerebrospinal fluid in effective concentrations.

TOXICITY AND SIDE EFFECTS

Crystalluria, with renal blockage, is a problem with some of the less soluble compounds, including sulfadiazine and sulfathiazole, especially if excessive dosage is used. Rashes are common and erythema multiforme (Stevens–Johnson syndrome) is a rare, but potentially life-threatening complication. Serious hematological effects are also seen occasionally. Fears of toxicity have led to major reductions in their use in the UK over the past decade, although this has not been the case in most other countries. Their activity (alone and in combination with trimethoprim) against most epidemic strains of MRSA may well see them being used increasingly in the future.

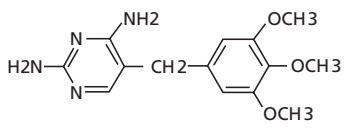
Diaminopyrimidines

STRUCTURE AND SPECTRUM OF ACTIVITY

This family of synthetic pyrimidine derivatives includes trimethoprim, the most familiar member of the group (Figure 17), and the closely related antibacterial agents, tetroxoprim and brodimoprim which are in use in some countries, but offer little, if any, advantage over trimethoprim. Also related are the antimalarial agents pyrimethamine and cycloguanil (the in vivo metabolite of proguanil), the antipneumocystis agent, trimetrexate and the anticancer drug, methotrexate.

Trimethoprim and its congeners are active against many gram-positive and gram-negative bacteria, but *P. aeruginosa*, *B. fragilis*, chlamydiae, rickettsiae, mycoplasmas, and mycobacteria are outside the spectrum. Although they exhibit excellent activity in their own right, they are often formulated with sulfonamides, with which they interact synergically, at least in vitro. Among such combination products are: co-trimoxazole (trimethoprim + sulfamethoxazole); co-trimazine (trimethoprim + sulfadiazine); co-trifamole (trimethoprim + sulfamoxole), and co-tetroxazine, (tetroxoprim + sulfadiazine).

Trimethoprim



Tetroxoprim

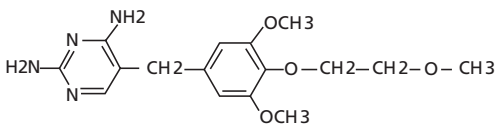


Figure 17 *Structures of trimethoprim and tetroxoprim.*

MODE OF ACTION

Diaminopyrimidines act on the same metabolic pathway as sulfonamides, but at a later stage. They inhibit dihydrofolate reductase, the enzyme that converts the precursor form of folic acid, dihydrofolate, to the active cofactor, tetrahydrofolic acid. The affinity of trimethoprim for bacterial dihydrofolate reductase is several thousand times greater than for the corresponding human enzyme. Tetrahydrofolic acid is an essential carrier molecule in many single-carbon transactions within cells and is usually regenerated unchanged. However, in one such transfer, the production of thymidylic acid from deoxyuridylic acid, diaminopyrimidines act as hydrogen donors, as well as methyl-group carriers and emerge from the reaction in the oxidized form, dihydrofolate. Trimethoprim and its relatives prevent regeneration of tetrahydrofolic acid and thus trap the vitamin in the unusable precursor form. Consequently, these drugs influence bacterial growth more quickly than sulfonamides, which rely on dilution of the folate pool to achieve their bacteristatic effect. In the presence of sufficient diaminopyrimidine to completely halt folate activity, the sulfonamides in combined formulations have no opportunity to interfere with bacterial growth, although they still contribute substantially to the overall toxicity of the mixtures.

RESISTANCE

The prevalence of resistance to trimethoprim has steadily increased since its introduction in 1969. Several mechanisms are recognized, the most common of which is attributable to mutations that lead to the production of altered dihydrofolate reductases (Towner 1992a; Huovinen et al. 1995).

PHARMACOLOGICAL PROPERTIES

Trimethoprim can be given by the oral and parenteral routes. It is widely distributed in tissues, including bronchial secretions. Concentrations achieved in cerebrospinal fluid are about 30–50 percent of the corresponding plasma level. Excretion is almost entirely renal, partly as metabolites, some of which retain antibacterial activity. The plasma half-life is about 10 h and it is less than 50 percent protein bound.

TOXICITY AND SIDE EFFECTS

Trimethoprim is well tolerated and most of the side effects of co-trimoxazole are usually attributable to the sulfonamide component. Nevertheless, trimethoprim itself may give rise to idiosyncratic reactions. The potential for exacerbating folate deficiency can normally be countered with folate supplements, but the drug is not recommended in pregnancy.

Quinolones

STRUCTURE AND SPECTRUM OF ACTIVITY

The quinolones are a large family of compounds (Table 6), the molecular similarity of which is based on the quinolone nucleus, or related naphthyridine, cinnoline or pyridopyrimidine structures (Smith and Lewin 1988) (Figure 18). The first member of the group to be used in therapy, nalidixic acid, is a naphthyridine derivative with a narrow spectrum of activity directed almost exclusively against enterobacteria. With the addition of a fluorine atom at C-6 and a piperazine substituent at C-7, the intrinsic activity and spectrum were substantially altered. Norfloxacin is about 50 times more active than nalidixic acid against sensitive enterobacteria and also exhibits some activity against gram-positive cocci and *P. aeruginosa*. Other derivatives with the 6-fluoro-7-piperazinyl substitutions (now collectively called fluoroquinolones) followed. Ciprofloxacin and ofloxacin offer further improved activity, and recent derivatives such as levofloxacin, moxifloxacin, gatifloxacin, and gemifloxacin have been developed with improved antipneumococcal activity, in response to the world-wide epidemic of PRP. Unfortunately, many other agents in development have dropped by the wayside because of potential neuro, cardiac, and photo-associated toxicity. Certain closely related compounds, including enrofloxacin and sarafloxacin are used in veterinary practice.

Some of the more active quinolones, including ciprofloxacin and ofloxacin, exhibit activity against chlamydiae (Oriel 1989) and mycobacteria (Garcia-Rodriguez and Gomez Garcia 1993), but this does not always translate into therapeutic success (Oriel 1989; Young 1993).

The activity is variably affected by pH (the activity usually being reduced at acid pH values) and by the presence of magnesium and other cations (Smith and Lewin 1988).

MODE OF ACTION

The primary site of action of quinolones is DNA gyrase (topoisomerase II), the remarkable enzyme that engineers the breaking and rejoining of supercoiled DNA. The action mainly involves the DNA gyrase A subunit, although the B subunit can also be affected by some quinolones (Hooper and Wolfson 1989).

RESISTANCE

Resistance to earlier quinolones of the nalidixic acid type occurs readily by chromosomal mutation and restricts the value of these compounds in the treatment of complicated urinary tract infection (Greenwood and O'Grady 1977). Such resistance also affects newer fluoroquinolones, but the reduction of activity is such that variants resistant to nalidixic acid are still inhibited by concentrations achievable therapeutically. Early

Table 6 *Proposed mechanisms of fluroquinolone resistance, by organism*

	Drug-target mutations in DNA gyrase or topoisomerase IV

Cpfx, ciprofloxacin; Gtfx, gatifloxacin; Lvfx, levofloxacin; Nrfx, norfloxacin; Spfx, sparfloxacin; Tvfx, trovafloxacin.
a) Antimicrobials to which the amino acid alterations in the enzyme confer resistance. For many bacteria, the basic resistance mechanism applies for all quinolone agents. However, in some bacteria, such as *S. pneumoniae*, the resistance mechanism will vary depending on the type of quinolone, as indicated here for Cpfx and Spfx.
b) Several different types of active efflux mechanisms exist; these data indicate only whether an active efflux mechanism of resistance has been found in a bacterial organism.
c) No or unknown (after Goldstein and Garbaedian-Ruffalo 2002).

optimism that this, together with the presence of only two convincing reports of plasmid-mediated resistance (Jacoby et al. 2003; Martínez-Martínez et al. 2003) would reduce the likelihood of resistance to fluoroquinolones becoming widespread, have not been realized. As might be expected, the emergence of resistance is particularly common in bacteria, such as *P. aeruginosa*, *Campylobacter jejuni*, and *S. aureus*, for which the minimum inhibitory concentration of fluoroquinolones does not greatly exceed therapeutically achievable concentrations (Wolfson and Hooper 1989; Peterson 1994; Wiedemann and Heisig 1994). Resistance is usually due to sequential mutations in genes for DNA gyrase, but may also follow from alterations in drug accumulation, sometimes associated with alterations in outer-membrane proteins of gram-negative bacilli (Wolfson and Hooper 1989). Early quinolones, which are innately less active, select well for first-step mutations, as these lead to resistance. Although new quinolones remain active, their MICs are raised, making second-step mutations more likely to occur, giving resistance to these new agents. Consequently, there have been calls to stop using these older agents, but this is probably not realistic because of cost. Also, it suggests a narrow view of the effects of antibiotics to make such calls. The targeted pathogen will not be the only bacteria exposed to the new agents – of necessity the whole bacterial flora will be exposed with unknown consequences in terms of resistance. An outbreak of a nalidixic acid resistant *S. dysenteria* with intermediate susceptibility to cipro-floxacin has recently been reported (Sarkar et al. 2003).

PHARMACOLOGICAL PROPERTIES

Quinolones are generally well absorbed when given orally, but some fluoroquinolones, including ciprofloxacin and levofloxacin, are also available in parenteral formulations. Nalidixic acid and the early congeners are extensively metabolized in vivo and sufficient unchanged drug to achieve an antibacterial effect is found only in urine. Fluoroquinolones are, in general, less susceptible to metabolic changes and since they are well distributed in the body including bile, they are of value in many systemic infections. Plasma elimination half-lives of the fluoroquinolones are prolonged, allowing once or twice daily dosing. Protein binding is low.

TOXICITY AND SIDE EFFECTS

They are generally well tolerated, although rashes, gastrointestinal upsets, and photosensitivity may occur and there are persistent reports of occasional neurotoxic side effects (Hooper and Wolfson 1991; Midtvedt and Greenwood 1994). The observation that

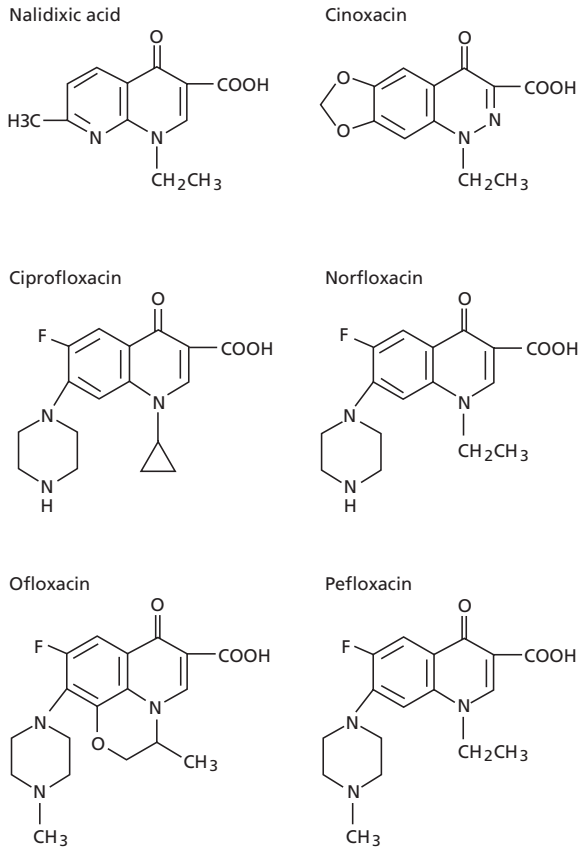

Figure 18 *Structures of some quinolones.*

fluoroquinolones can cause arthropathy in young experimental animals has led to a recommendation that these drugs should be avoided in young children and in women of child-bearing age. Cases of Achilles tendinitis, sometimes with rupture of the tendon, have been reported (Ribard et al. 1992).

Rifamycins

STRUCTURE AND SPECTRUM OF ACTIVITY

The rifamycins that are most widely used clinically, rifampin (Figure 19) and rifabutin (also known as ansamycin), are semisynthetic derivatives of the naturally occurring antibiotic, rifamycin B. Rifampin exhibits good activity against gram-positive and gram-negative cocci, particularly staphylococci, but is more noted for its antimycobacterial activity. Gram-negative bacilli are much less susceptible. Rifabutin has been introduced specifically because of its activity against organisms of the *M. avium* complex. Rifampin is seeing increased use in combination therapy for MRSA, particularly where medical treatment of prosthetic implant infection is being attempted, as it is thought to retain bactericidal activity in this setting (Widmer 2001).

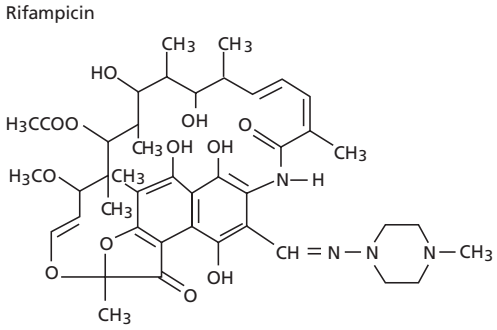

Figure 19 *Structure of rifampin.*

MODE OF ACTION

Rifampin and other rifamycins bind to the subunit of DNA-dependent RNA polymerase and prevent initiation of RNA synthesis (Wehrli and Staehelin 1971).

RESISTANCE

Resistance caused by mutational alterations in the target enzyme arises readily and may be a cause of treatment failure if rifampin is used alone. In tuberculosis and leprosy, in which rifampin is normally used in combination with other drugs, resistance is presently uncommon, although multiply-resistant strains of *M. tuberculosis* are causing concern in some places (Warburton et al. 1993; Young 1993; Pablos-Mendez et al. 1998).

PHARMACOLOGICAL PROPERTIES

Rifampin is very well absorbed when given by mouth, but the bioavailability of oral rifabutin is variable (Skinner et al. 1989). Both drugs are well distributed and excreted primarily by the hepatobiliary route, but also renally. They impart a red color to the urine and to tears, so that they may discolor soft contact lenses. They are potent inducers of liver enzymes, which promote self-metabolism of the antibiotics, as well as that of other drugs, including oral contraceptives and warfarin. There is significant binding to plasma proteins (approximately 70 percent). The terminal half-life of rifabutin (approximately 36 h) is much longer than that of rifampin (approximately 3.5 h).

TOXICITY AND SIDE EFFECTS

Rifampin may cause sensitization when used intermittently, as in some recommended regimens for the treatment of tuberculosis. Gastrointestinal upsets, jaundice, and (particularly with rifabutin) hematological effects are recognized. Induction of microsomal liver enzymes may lead to important interactions with other drugs, including failure of oral contraception.

Nitroimidazoles

STRUCTURE AND SPECTRUM OF ACTIVITY

Azole derivatives of various kinds have wide-ranging antimicrobial activities against fungi, protozoa, and helminths, as well as bacteria. Some may have a role as radiosensitizing agents in cancer therapy. Those that exhibit useful antibacterial activity are 5-nitroimidazoles. Only two, metronidazole and tinidazole (Figure 20), are used in human medicine in the UK, but others, such as nimorazole, ornidazole, and secnidazole, are available elsewhere and yet more are used in veterinary practice. They are primarily antiprotozoal agents, but also exhibit potent activity against anaerobic bacteria. Metronidazole offers a useful alternative to vancomycin in the treatment of *C. difficile*-associated colitis.

Microaerophiles and oxygen-tolerant species, such as *Actinomyces* spp. and *Propionibacterium* spp., are mostly insensitive (Greenwood et al. 1991), though metronidazole is used successfully in infections with *H. pylori* and *Gardnerella vaginalis*.

MODE OF ACTION

The narrow spectrum of activity of 5-nitroimidazoles arises because the antibacterial effect is dependent on reduction of the nitro group under anaerobic conditions. The compounds capture electrons from reduced ferredoxin generated in the course of the decarboxylation of pyruvate by the pyruvate–ferredoxin oxidoreductase complex. The short-lived reduction product kills the cell, probably by inducing breaks in the DNA strands (Edwards 1993a). The anomalous susceptibility of certain microaerophiles remains unexplained, although there is evidence that it is related to unusual metabolic pathways in these organisms (Smith and Edwards 1995).

RESISTANCE

Resistance to metronidazole and other 5-nitroimidazoles remains very uncommon despite the widespread use of these compounds. Some reports have subsequently been shown to have been erroneous because sensitivity tests were carried out under inadequately anaerobic conditions. There are, nevertheless, well documented accounts of resistance in clinical isolates of *B. fragilis* and other anaerobes, usually associated with a decreased ability to reduce the drug (Edwards 1993b).

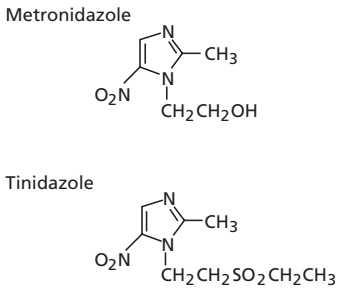

Figure 20 *Structures of metronidazole and tinidazole.*

PHARMACOLOGICAL PROPERTIES

Metronidazole is usually administered by mouth, though intravenous, suppository, and topical preparations are also available for various purposes. Tinidazole is available in the UK only in tablet form. They are virtually completely absorbed by the oral route and are widely distributed, including into cerebrospinal fluid. Plasma protein binding is negligible. Tinidazole has a somewhat longer half-life than metronidazole (12–14 h versus 8–10 h). Both are metabolized and excreted chiefly into urine, partly as glucuronide conjugates.

TOXICITY AND SIDE EFFECTS

Nausea and abdominal cramps occur quite frequently; various other side effects have been reported occasionally. Patients often complain of dryness in the mouth and a metallic taste. Alcohol should be avoided because of a disulfiram-like reaction. Fears that the effect of metronidazole on DNA might lead to mutagenic or teratogenic effects in humans have not been borne out in practice (Morgan 1978; Beard et al. 1979). It is, nonetheless, considered prudent to avoid using these drugs during pregnancy, particularly during the first trimester.

Nitrofurans

STRUCTURE AND SPECTRUM OF ACTIVITY

Various nitrofuran derivatives are in use around the world as antibacterial agents, including furazolidone and nifuratel (which are said to possess antiprotozoal, as well as antibacterial activity) and nitrofurazone. However, the most widely used agent of this type, and the only one available in the UK, is nitrofurantoin (Figure 21), which is used as a urinary antiseptic. Nitrofurantoin is bactericidal to most urinary pathogens at concentrations achievable in urine, although activity against *Proteus* spp. is unreliable, partly because the drug is less active in the alkaline conditions produced by urea-splitting organisms. Many strains of MRSA are susceptible.

MODE OF ACTION

Like the nitroimidazoles, the nitrofurans are susceptible to nitroreductases, though in this case reduction takes place in an aerobic environment. The most likely explanation for the bactericidal action of these drugs is, therefore, that a reduced intermediate causes DNA strand breakage in a manner analogous to that of nitroimidazoles. This suggestion has the attraction of accounting for the known mutagenic effects of these compounds in vitro (McCalla 1977). However, more recently it has been suggested that reactive nitrofurantoin metabolites interfere not with DNA but with protein synthesis

Nitrofurantoin

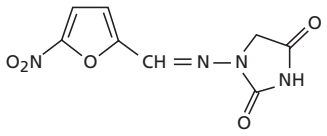

Figure 21 *Structure of nitrofurantoin.*

(McOsker and Fitzpatrick 1994). These authors also suggest an alternative mechanism of action that does not depend on bacterial nitroreductases.

RESISTANCE

Acquired resistance in susceptible bacterial species is uncommon and, even when it does occur, is rarely plasmid mediated. For this reason multiresistant strains of enterobacteria usually remain susceptible to nitrofurantoin.

PHARMACOLOGICAL PROPERTIES

Nitrofurantoin is administered by mouth and is rapidly and almost completely absorbed. It is excreted extremely rapidly into urine (half-life 20–60 min) and such drug, as finds its way into body tissues, is metabolized to the inactive derivative, aminofurantoin.

TOXICITY AND SIDE EFFECTS

Nausea is the most frequent complaint of patients receiving nitrofurantoin, but this is less common with a macrocrystalline formulation. Among less common side effects, pulmonary complications are prominent, but even these are rarely seen. The mutagenic potential of nitrofurans has not prevented their widespread and evidently safe use, even in pregnancy.

Novobiocin

Novobiocin is a naturally occurring antibiotic related to the coumarin anticoagulants. It acts on the B subunit of bacterial DNA gyrase. It is quite active against staphylococci and streptococci, but not Enterobacteriaceae or pseudomonads. It was formerly used principally as an antistaphylococcal agent, but toxicity has limited its value. Multiresistant staphylococci may remain susceptible to novobiocin, but mutations to resistance occur readily.

AGENTS THAT ACT ON THE BACTERIAL CELL MEMBRANE

In contrast to antifungal agents, in which the cell membrane is the most common target, few antibacterial agents act at this level, and those that do are quite toxic. Among membrane-active agents used in human medicine, only the polymyxins have been regularly used systemically.

Polymyxins

STRUCTURE AND SPECTRUM OF ACTIVITY

The polymyxins are a family of antibiotics produced by species of *Bacillus*. They are made up of a polypeptide portion, much of which is arranged in a cyclic fashion, with a hydrophobic octanoic acid tail (Figure 22). Two members of the family are in therapeutic use: polymyxin B and colistin (polymyxin E). Derivatives in which the diaminobutyric acid residues are sulfomethylated are also available. These sulfomethyl polymyxins exhibit reduced antibacterial activity, but they spontaneously break down to the more active parent compounds. Most gram-negative bacilli (with the exception of *Proteus* spp.) are sensitive to polymyxins, but their chief attraction is their activity against *P. aeruginosa*. Gram-positive organisms are much less susceptible.

MODE OF ACTION

The polymyxins act like cationic detergents to destabilize the cytoplasmic membrane. They also act on the outer membrane of gram-negative bacilli by binding to lipopolysaccharide. Polymyxin B nonapeptide, a derivative in which the fatty acid tail has been removed, binds to lipid A of lipopolysaccharide (but not to the cytoplasmic membrane) and has attracted some attention because of its anti-endotoxin properties (Danner et al. 1989).

RESISTANCE

Primary resistance in sensitive species is uncommon. However, adaptation to resistance readily occurs when dense bacterial populations are exposed to the drug (Greenwood 1975). This type of resistance is readily reversible and is apparently due to phenotypic changes in the membrane structure (Gilleland et al. 1984).

PHARMACOLOGICAL PROPERTIES

Polymyxins are nowadays more widely used as topical than as systemic agents. Polymyxin B, in particular, features as an ingredient of a number of topical preparations. They are not absorbed when given by mouth, but oral suspensions of colistin are used in several selective digestive tract decontamination regimens in neutropenic patients (Donnelly 1993). After injection of parenteral preparations, the polymyxins bind to tissue cells, but sulfomethyl derivatives are less readily bound and are excreted more rapidly. They do not penetrate into cerebrospinal fluid. They are excreted renally with a half-life of about 6 h, but tissue binding ensures that much of the dose is retained for much longer periods. Protein binding is low.

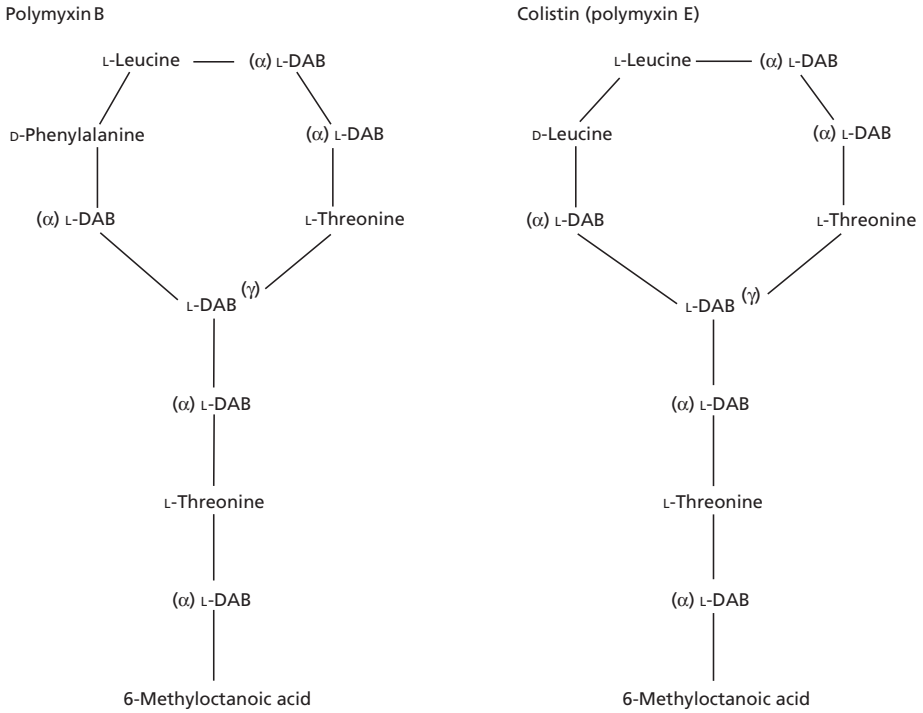

Figure 22 *Structures of polymyxin B and colistin (polymyxin E). In the sulfomethyl derivatives each of the β-linked diaminobutyric acid (DAB) residues may be sulfomethylated.*

TOXICITY AND SIDE EFFECTS

The major toxicity problems of the polymyxins relate to their affinity for cell membranes, including those of mammalian cells. Nephrotoxicty and neurotoxicity occur, but are usually reversible. Sulfomethyl polymyxins are somewhat less toxic than the sulfates. Topical preparations are generally well tolerated.

Other agents acting on bacterial membranes

Several antibiotics that are found in topical formulations, including gramicidin and tyrocidine, interfere with the integrity of bacterial cell membranes. Similarly, a number of agents used in animal husbandry, including valinomycin and monensin, achieve their effect at the membrane level. These agents act as ionophores: compounds that form transmembrane channels with consequent leakage of cellular potassium and other cations (Pressman 1973).

In addition, many antiseptics and disinfectants disrupt bacterial membranes. Naturally occurring antimicrobial peptides that are widespread in nature, such as the magainins, cecropins, defensins, and the lanthionine-containing lantibiotics, also act selectively on cell membranes (Boman et al. 1994). There has been much interest in these and related synthetic oligopeptides, but any possible future for these compounds as therapeutic agents is still some way off.

LABORATORY CONTROL OF ANTIMICROBIAL CHEMOTHERAPY

The performance of antimicrobial sensitivity tests and antibiotic assays are among the most important functions of medical microbiology service laboratories. Similarly, the provision of advice to clinicians and to hospital therapeutics committees on the use of antimicrobial agents forms a crucial part of the role of the clinical microbiologist. Indeed, it is essential that this role is expanded if rational antibiotic use is to be encouraged and the threat of multidrug resistance is to be kept at bay. In addition, the microbiology laboratory provides an important service in monitoring local trends of antibiotic drug resistance and in disseminating this information to prescribers (Greenwood 1993).

Sensitivity test methods

ANTIBIOTIC TITRATIONS

The intrinsic activity of antimicrobial drugs in vitro is usually expressed in terms of the minimum inhibitory concentration (MIC); less commonly by the minimum bactericidal concentration (MBC). These values are derived by titration of the drug against a standard inoculum of a pure culture of an isolated bacterial species in broth or on agar plates. The MIC is the lowest concentration that prevents the development of visible growth after a period of incubation that is usually

16–20 h for most common pathogens, but may be longer for slow-growing organisms. The MBC is assessed from broth titrations by subculture of those dilutions of antibiotic that are above the MIC. The lowest concentration of antibiotic that achieves a 1 000-fold or greater reduction in the original bacterial inoculum (i.e. a fall in viable count of at least 3 $\log_{10}$ colony-forming units) is generally taken as the MBC. The rate of killing may be more important than the overnight MBC value. In this case it is necessary to count the number of viable organisms at regular intervals after exposure to appropriate concentrations of the antimicrobial agent. In assessing viability it is good practice to specify colony-forming units rather than bacterial numbers, since bacteria may grow in clumps or chains that give rise to single colonies on solid media.

Alternatively, the E-test, in which a linear gradient of antibiotic is carried on a special strip applied to a plate inoculum of the test organism, can be used. This method is very simple and appears to correlate well with more traditional methods (Baker et al. 1991; Brown and Brown 1991).

Although MIC titrations provide figures that are widely used in comparing the activity of different antimicrobial agents, the results may be extremely variable depending on the test conditions and on the bacterial inoculum (Amsterdam 1991). Moreover, the factors determining the end point of MIC titrations vary from drug to drug and from organism to organism (Greenwood 1981). Selected MIC values shown in Table 7 should be interpreted in the light of these provisos. Nevertheless, the MIC is the mainstay of modern pharmacodynamic principles on the best antibiotic dosing schedules and is certainly the single most important measure of an antibiotic's activity.

MIC titrations are generally too time-consuming for routine purposes, although prepared microtitration trays containing suitable dilutions of lyophilized antibiotic can be used to simplify the procedure.

DISK DIFFUSION METHODS

Most medical microbiology laboratories use one of the disk diffusion techniques in which antibiotics incorporated into absorbent disks are applied to the surface of culture plates seeded with the test organism (Acar and Goldstein 1991; Brown 1994). Antibiotic diffuses rapidly from the disk into the surrounding medium, setting up a concentration gradient of the drug. The edge of a zone of inhibition is formed where the concentration is able to prevent visible growth of the microorganism (Barry 1991).

In the USA and world-wide, a highly standardized disk method previously known as the Kirby–Bauer test and now known as the NCCLS method (NCCLS 2000, 2002) is widely used. In the UK it is more usual to use Stokes' comparative disk method, in which the test and control organism are both exposed to the gradient of antibiotic under identical conditions on the same plate (Stokes et al. 1993). Stokes' method is particularly useful in conditions such as exist in many developing countries in which refrigeration facilities are unreliable, so that disks are kept in unsatisfactory, often humid conditions. More standardized methods, such as NCCLS, and the recently described BSAC method are increasingly adopted (BSAC Working Party Report 2001). This is because of the increasing need for comparable surveillance data in the battle against antibiotic resistance. If zone sizes are accurately measured then subtle changes that may become significant over a period can be more easily spotted. Steps can then be taken to reverse such trends before they become a clinical problem.

By comparing disk zone sizes and MIC values for many different organisms, a relationship between the two is evident and this can be formalized by regression analysis. However, since the factors that determine the end point of MIC titrations differ considerably from those that operate in the conditions of the disk diffusion test, the relationship is less than perfect. This is particularly true for those organisms that are of intermediate susceptibility, for which there may be wide discrepancies between the two methods.

BREAKPOINT METHOD

Many laboratories with large workloads find it convenient to use the breakpoint method of sensitivity testing, since this allows many isolates of bacteria to be tested together. In this method, antibiotics are incorporated into agar plates at predetermined 'breakpoint' concentrations based on therapeutically meaningful levels. Plates are spot-inoculated with a multipoint inoculation device and incubated overnight. If no growth occurs at the breakpoint concentration, the organism is scored as sensitive; if growth occurs, the organism is regarded as resistant. Sometimes a second, higher breakpoint is also used in order to establish a category of 'reduced susceptibility'. By use of a plate scanner to read the result, the whole method can be semi-automated.

OTHER METHODS OF SENSITIVITY TESTING

Many different mechanized or semi-automated methods have been devised for determining MICs or otherwise estimating the sensitivity status of bacteria (Tilton 1991). Some of these machines produce results much more rapidly than traditional methods, but the correlation is often less than perfect, partly because of the requirement for reading the end point turbidimetrically (Greenwood 1985).

DNA probes that are able to detect the genetic potential for resistance have also received much attention in recent years. These methods need to be refined if they are to be of use as routine methods, since most probes are too specific to detect the wide range of resistance

Table 7 *Activity in vitro of some representative antibacterial agents against selected micro-organisms*

These minimum inhibitory concentrations refer to typical values for fully susceptible strains without acquired resistance traits. In using this table it should be borne in mind that inhibitory concentrations may vary considerably depending on the conditions of the test and the bacterial inoculum used. R, intrinsically resistant (agent has no useful activity).

a) *C. pneumoniae*.

mechanisms that may be present. Moreover, the presence of a resistance gene does not guarantee that it will necessarily be expressed (Towner 1992b). Nonetheless, DNA probes offer an attractive solution to the problem of detecting specific resistance mechanisms, particularly in organisms that are difficult to grow and are already in clinical use for rapid detection of MRSA and rifampin resistance in *M. tuberculosis* (Fluit et al. 2001; Holliman and Johnson 1998).

CLINICAL RELEVANCE OF ANTIBIOTIC SENSITIVITY TESTS

A laboratory report indicating in vitro susceptibility of a microorganism to a particular agent by no means ensures that a therapeutic response will be achieved if that drug is used in treatment. Much will depend on the type of infection, the condition of the patient, and the pharmacological properties of the drug. A statement about in vitro resistance is more likely to indicate that treatment with that agent will not influence the course of infection, although the patient may recover for other reasons: for example, through the influence of normal host defense mechanisms, by the surgical drainage of a collection of pus, or by the removal of a catheter.

In vitro susceptibility tests by their very nature offer only a crude approximation to the complex situation that exists in the infected patient. Laboratory reports merely provide information that needs to be interpreted thoughtfully in the light of the limitations of the tests and the condition of the individual patient (Slack 1995a).

Antibiotic assays

INDICATIONS FOR ANTIBIOTIC ASSAY

Aside from the need to establish the pharmacokinetic behavior of antimicrobial drugs in the early stages of their development, indications for the assay of antimicrobial agents in clinical practice are few. The most common grounds for antibiotic assay are provided by those agents, pre-eminently the aminoglycosides, in which the therapeutic range (the difference between an effective concentration and a toxic concentration) is relatively narrow. With such agents, dosage is often initiated by use of a nomogram that takes account of the sex-related creatinine concentration (a measure of renal function), body weight, and age of the patient (Mawer et al. 1974). Assays are subsequently performed 1 h after the dose, to establish that an adequate peak concentration of the drug has been achieved, and just before the next dose ('trough' concentration) to check that drug accumulation has not occurred (Humphreys and Reeves 1991). In once-daily dosing of aminoglycosides a level between 6 and 14 h post dose is recommended. Reference is then made to a monogram to calculate the dosing schedule (Nicolau et al. 1995).

Other antibiotics that may require laboratory assay during drug therapy include the glycopeptides (although the need for this has been disputed: Ackerman 1994; Cantú et al. 1994) and chloramphenicol in young infants who may be in danger of 'gray baby' syndrome through an immature capacity to metabolize the drug.

ASSAY METHODS

Traditional plate diffusion methods of antibiotic assay have largely been superseded by automated immunoassay procedures that are more specific, more accurate, and much more rapid. High pressure liquid chromatography methods are also available for most antimicrobial agents. They are useful for certain purposes, since metabolites can often be identified and quantified by this means, but they are too cumbersome for routine use. The various assay methods that are in use are described in detail by Chapin-Robertson and Edberg (1991) and Reeves et al. (1999).

SERUM BACTERICIDAL TEST

A type of antibiotic assay commonly called back-titration, in which the bactericidal activity of the patient's serum is titrated against the organism responsible for the infection, is sometimes used in conditions in which it is important to achieve a bactericidal effect (usually because of poor host immune response). The test is commonly used in the management of infective endocarditis and is also sometimes recommended in other types of infection, including osteomyelitis, cystic fibrosis, and sepsis in immunocompromised patients. Peak (usually 1 h after administration of the dose) and trough (immediately before the next dose) concentrations are assayed. The bactericidal end point is measured by subculture of dilutions of patient's serum that inhibit growth of the organism during overnight incubation. The result may reflect the activity of more than one agent if combination therapy is being used.

The value of the serum bactericidal test has been questioned, not least because of the many technical variables that may affect the result (Peterson and Shanholtzer 1992). Moreover, clinical correlates with successful therapy have been hard to come by, although a peak serum bactericidal titer >32, and a trough <16 are usually associated with a bacteriological cure. Performance of these tests is no longer recommended in the treatment of infective endocarditis in the UK (Shanson 1998).

CONCLUSIONS

The twentieth century has seen unprecedented advances in the treatment of infection. More than 250 individual compounds are now on the world market for the systemic treatment of bacterial infection. However, the process of drug discovery and development is now so

costly and the return so uncertain that it is unlikely that this abundance will be matched in the next century (Billstein 1994). Already pharmaceutical companies are turning their attention from antibacterial agents to the potentially more profitable areas of antiviral and antifungal compounds. At a recent meeting it was apparent that six major pharmaceutical companies had recently decided to cease their antibiotic programmes and another two to downgrade or sell them off (Shlaes, 2003).

The ability of the drug companies to come up with new and ever more potent agents has, until now, blunted the impact of bacterial resistance and weakened our resolve to preserve the value of antibiotics by circumscribing their use. Such wastefulness can no longer be afforded. The second half of the twentieth century was truly a golden age of antibiotics. The future is largely in the hands of the prescriber.

BLOODSTREAM INFECTION

INTRODUCTION

Bloodstream infections (BSI) are a major cause of morbidity and mortality. Based on data from death certificates, these infections represent the tenth leading cause of death in the United States (NNIS 2003), and the age-adjusted death rate has risen by 78 percent over the past two decades (NNIS 2000). The true incidence may even be higher. Assuming that 5 percent of hospitalized patients develop an infection, of which 10 percent are bloodstream infections, with an attributable mortality rate of 15 percent, nosocomial bloodstream infections would represent the eighth leading cause of death in the United States (Wenzel and Edmond 2001). Approximately 250 000 cases of nosocomial bloodstream infection occur annually in the United States (Pittet et al. 1997). Recent studies reported the incidence of BSI to be between 1 percent in intensive care unit (ICU) patients (Warren et al. 2001) and 36 percent in bone marrow transplant patients (Collin et al. 2001). A recent survey reported an overall incidence of six cases of BSI per 1 000 hospital admissions, with pathogen specific attack rates between 0.1 and 1.6 per 1 000 admissions (Wisplinghoff et al. 2004). In ICU patients, incidences between 32 and 54 BSI per 1 000 ICU admissions have been reported (Daschner et al. 1982; Pittet et al. 1996; Darby et al. 1997; Edgeworth et al. 1999). The crude mortality associated with BSI ranges from 12 percent in general hospital populations to 80 percent in ICU patients (Weinstein et al. 1983a; Pittet et al. 1993; Pittet et al. 1994; Digiovine et al. 1999; Warren et al. 2001). The mortality directly attributable to BSI in these populations has been estimated to be between 16 and 40 percent (Pittet et al. 1994; Digiovine et al. 1999). In ICU patients with BSI, the length of stay is prolonged by 7.5 to 25 days and the total hospitalization time by 4.5 to 32 days (Pittet et al. 1994; Digiovine et al. 1999; Warren et al. 2001). Inappropriate empirical antimicrobial therapy is an important predictor of death in patients with BSI (Bryan et al. 1983; Pittet et al. 1994; Kollef and Fraser 2001).

Throughout the 1960s and 1970s, gram-negative organisms were most frequently isolated from patients with BSI. Since then, gram-positive organisms have become increasingly frequent (Edmond et al. 1999; NNIS 2000; Diekema et al. 2002; Wisplinghoff et al. 2004).

Usually bacteremia or BSI originates from a localized infection at a distant site. Such a secondary BSI can

usually only be cured if the site of origin is identified and treated which often requires surgical intervention. Therefore, it is highly important for both clinicians and laboratory personnel to consider and evaluate all possible sources of BSI.

Clinical presentation ranges from benign transient bacteremia with little or no symptoms to fulminant septic shock with high mortality. Transient bacteremia may follow manipulation of or surgery in infected or colonized areas. Intermittent bacteremia is usually seen secondary to abscesses, mostly abdominal or pelvic. Continuous bacteremia is associated with endocarditis and other intravascular infections, but may also occur in the first weeks of typhoid fever or brucellosis. In patients with intermittent or continuous BSI, fever is the most common symptom, followed by other unspecific signs of systemic disease, such as elevated heart and respiratory rate, fatigue, malaise, or failure to thrive in neonates. A substantial proportion of patients with infection may also be euthermic or hypothermic and may present with nondescript clinical conditions. Additional symptoms may develop due to metastatic foci, such as seizures or altered personality or level of consciousness.

In addition to the significant health and economic impact of true BSI, vast resources are also consumed by false-positive blood culture (BC) results. Overall, BCs have a relatively low yield and the proportion of false-positive results is high (Shafazand and Weinacker 2002). Studies in unselected patient populations found that between 7.5 and 12 percent of all BC are positive, and among these about 5 percent are considered contaminated (Weinstein et al. 1983b; Roberts et al. 1991; Darby et al. 1997). Recent studies found about 8.6 percent of blood cultures positive in the ICU, with 3.6 percent being due to contaminants (Schwenzer et al. 1994) while in unselected patient populations 14 percent of all blood cultures were positive with 38 percent of those being due to contaminants (Moser et al. 1998). False positive BCs may increase diagnostic testing, antibiotic use, and prolong hospitalization (Shafazand and Weinacker 2002). Bates et al. (1991) showed that false-positive blood cultures increased the length of stay by a median of 4.5 days, and generated additional hospital, pharmacy, and laboratory charges. Some studies have developed rules to assess the probability of BSI in patients prior to obtaining BCs. The clinical value of these rules remains questionable, since some are retrospective or evaluate subsets of patients only (Shafazand and Weinacker 2002).

DEFINITIONS

Even though definitions for most terms used in the context of BSI are exact, there is still confusion due to imprecise and interchanging usage of these terms. Bacteremia or fungemia denote the presence of viable bacteria or fungi in the blood, with or without clinical symptoms. In contrast, systemic inflammatory response syndrome (SIRS) is a clinical term, defined as the presence of at least two of the following: temperature >38°C or <36°C, respiratory rate >20/min or $PaCO_2$ <32 Torr, heart rate >90/min, and leukocytes >12.0 × 10^9/l or <4.0 × 10^9/l or >10 percent bands. Of note, SIRS is independent of the presence of pathogens in the bloodstream. The combination of SIRS with bacteremia or fungemia is called sepsis, severe sepsis, depending on the additional presence of signs of organ dysfunction, such as hypotension or hypoperfusion, i.e. metabolic acidosis, altered mental status, oliguria, or acute respiratory distress syndrome. For detailed definitions, see Table 1. Septic shock is defined as severe sepsis with hypotension that is unresponsive to fluid resuscitation. To assess the extent of organ dysfunction, other scores such as the sequential organ failure assessment (SOFA) score (Vincent et al. 1998) may also be used. Recently, the Sepsis Definition Conference (Society of Critical Care Medicine, European Society of Intensive Care Medicine, American College of Chest Physicians and the Surgical Infection Societies) proposed the PIRO concept to classify sepsis, which is based on predisposing factors, infection, response, and organ dysfunction (Vincent 2002; Levy et al. 2003a). Bloodstream infection is frequently used interchangeably with sepsis, but is not as exactly defined, denoting bacteremia with clinical symptoms. Septicemia is an outdated term that was previously used to describe the systemic symptoms caused by bacteria, fungi or their toxins in the blood.

A bacteremia or BSI is called primary if the point of entry or focus cannot be determined, or if it originates from an intravascular catheter. The latter is also referred to as catheter-related BSI. Recent studies have recommended differentiating catheter-related bacteremia from both primary and secondary bacteremia (Renaud and Brun-Buisson 2001). If a distant site other than an IV catheter can be established as the point of origin, BSI is referred to as secondary. A distant site is usually confirmed to be the focus, if the same pathogen (with the same resistance pattern) is isolated from the blood culture and the primary site of infection.

Another way to classify BSI is by the time or setting of acquisition, i.e. community-acquired or nosocomial BSI. Usually community-acquired BSI is defined as a BSI that is detected (onset of symptoms) within the first 48 h after admission, while BSI is referred to as nosocomial if detected more than 48 h after admission. In recent years the number of people with frequent healthcare contacts, including those receiving healthcare including IV therapy at home or at a nursing home, has considerably increased. Therefore it may be more accurate to differentiate between nosocomial BSI (detected >48 h after admission), healthcare-associated BSI (detected <48 h after admission or during an outpatient visit in a patient with frequent healthcare contacts) and

Table 1 *Definitions*

Term	Definition
Bacteremia (fungemia)	Presence of viable bacteria or fungi in the blood, irrespective of clinical symptoms
SIRS	Systemic inflammatory response syndrome, defined as presence of at least two of the following: Temperature >38°C or <36°C Respiratory rate >20/min or $PaCO_2$ <32 Torr Heart rate >90/min Leukocytes >12 000/μl or <4 000/μl or >10% bands
Sepsis	SIRS with (proven or suspected) bacteremia (fungemia)
Severe sepsis	SIRS or sepsis with one or more signs of organ dysfunction, hypotension (systolic arterial pressure <90 mmHg) or hypoperfusion such as lactic acidosis (plasma lactate >2.0 mmol/l, altered mental status (GCS of 11 or below), renal failure (acute increase in serum creatinine >180 μmol/l; doubling in admission creatinine level in patients with chronic renal failure; requirement for acute dialysis or ultrafiltration), oliguria (urinary output <0.5 ml/kg per hour for at least 1 h or <30 ml for 2 h), disseminated intravascular coagulation (decrease in platelet count of 25% or more with any increase in prothrombin time), or adult respiratory distress syndrome (PaO_2/FiO_2 <175 with bilateral infiltrates consistent with pulmonary edema in the absence of heart failure; pulmonary capillary wedge pressure <18 mmHg if measured) (Rangel-Frausto et al. 1995)
Septic shock	Severe sepsis with hypotension that is unresponsive to fluid resuscitation and requires the administration of vasopressors
MODS	Multiple organ dysfunction syndrome; dysfunction of more than one organ
Septicemia	Outdated term, previously used for systemic symptoms caused by bacteria, fungi or their toxins in the blood

true community-acquired (detected <48 h after admission or during an outpatient visit in a patient with no or minor healthcare contacts). A recent study proposed to classify BSI as follows: true community-acquired BSI (detected within the first 48 h after admission, in patients who have not been hospitalized within the past 30 days and did not have a recent history of invasive procedures), BSI in recently discharged patients (2–30 days prior to the recent episode of BSI), BSI in patients with a recent history of invasive procedures (including insertion of Foley catheters, placement of intravascular catheters, long-term devices, central venous catheters, or dialysis), nursing home-acquired bacteremia, and true nosocomial BSI (detected >48 h after admission) (Siegman-Igra et al. 2002).

TECHNICAL ISSUES

Indications

Blood cultures are a valuable diagnostic tool and indicate whenever there is clinical evidence of sepsis or an unknown systemic infection (Aronson and Bor 1987). Signs of sepsis are shown in Table 2. Also, clinical suspicion of any infection that may be associated with bacteremia or fungemia such as meningitis, cholangitis, endocarditis, and osteomyelitis warrant the cultural examination of the patient's blood. In addition, blood cultures should be obtained in the following clinical conditions: pneumonia, pyelonephritis, septic arthritis, epiglottitis, and omphalitis (infants and neonates), as well as abscesses, and deep-seated or extended skin and soft tissue infections. Typhoid fever, brucellosis or leptospirosis can also be diagnosed by blood cultures (see below). Since neurological or psychiatric symptoms, such as seizures, acutely altered mental status, or TIA-like symptoms can be due to metastatic foci of BSI or secondary emboli following endocarditis, blood cultures are also highly recommended in these clinical situations. Blood cultures are also imperative in the diagnostic evaluation of fever of unknown origin since this may be caused by a chronic inflammatory process, such as an abscess associated with intermittent BSI. In critically ill patients, blood cultures should be performed in all patients with a new fever, even if the clinical findings do

Table 2 *Signs of sepsis (Vincent and Jacobs 2003)*

Category	Sign
General	Chills, fever or hypothermia, tachypnea or respiratory alkalosis, positive fluid balance
Inflammation	Leukocytosis or leukopenia, elevated CRP, IL-6, procalcitonin
Hemodynamic	Hypotension, tachycardia, centralization (cold extremities), oliguria, hyperlactatemia
Organ dysfunction	Hypoxemia, altered mental status, hyperglycemia, thrombocytopenia, altered hepatic function, altered renal function, nutritional imbalance

not strongly suggest an infectious cause (O'Grady et al. 1998). Furthermore, a substantial proportion of patients with infection are euthermic or hypothermic and may present with nondescript clinical symptoms. These include elderly patients or neonates, patients with open abdominal wounds or extensive burns, patients receiving extracorporal membrane oxygenation, or taking anti-inflammatory or antipyretic drugs (Vincent and Jacobs 2003). In these patients blood cultures can also be a valuable tool for detecting potentially life-threatening infection.

Blood cultures should be considered in an even broader range of situations in compromised patients with underlying conditions that predispose for BSI. This group of patients includes neonates (especially with low birth weight) and elderly patients, but also patients with neutropenia and other immunosuppressive conditions, patients with (artificial) grafts, especially vascular grafts or prosthetic valves, or intravascular access devices (central venous catheters or permanently implanted devices, such as ports or Hickman catheters). Patients in the setting of the ICU and patients hospitalized secondary to severe trauma or severe burns should also be considered in this context.

SPECIMEN COLLECTION AND TRANSPORT

The term 'blood culture' denotes a specific volume of blood which is aseptically drawn by a single venipuncture, inoculated into culture medium or media, and investigated for the presence of microorganisms. Usually an aerobic and an anaerobic vial are used, thus one blood culture – often also referred to as one blood culture set – would be equivalent to two bottles. Each blood culture should be obtained by a separate venipuncture (Smith-Elekes and Weinstein 1993). Obtaining blood cultures through indwelling intravascular catheters is generally not recommended, unless the involvement of the catheter as a source of BSI is to be investigated.

Disinfection

Since the rapid and reliable recovery of even small numbers of bacteria from the blood is the primary goal of blood cultures, the media also provide excellent growth conditions for contaminants and contamination poses a serious problem. False-positive blood culture results may lead to unnecessary, wrong, and potentially harmful antimicrobial therapy and increase length of stay and costs (Bates et al. 1991). In addition, an increasing number of true bacteremia and BSI in immunocompromised patients is caused by bacteria that are part of the common skin flora, such as coagulase-negative staphylococci (CoNS), corynebacteria, and *Bacillus* species. Correct interpretation of such findings largely depends on the assumption that proper aseptic techniques have been used for specimen collection and transport.

Blood must always be collected with a sterile needle and syringe or with a proprietary sterile system of needle and evacuated tube or bottle of blood culture medium. Thorough disinfection of the patient's skin is mandatory to reduce the contamination rate (Strand et al. 1993). For scrubbing of the venipuncture site, 70 percent alcohol or iodine solutions such as 10 percent povidone iodine or a 1–2 percent tincture of iodine or a combination of both has been recommended (Weinstein et al. 1983b; Strand et al. 1993; Dunne et al. 1997; O'Grady et al. 1998). Since none of the disinfectant solutions used to date works instantly, it is generally recommended to let the solution dry for at least 30 s before proceeding. Gloves should be worn by the operator after disinfection of the hands; some institutions even recommend sterile surgical gloves.

Time of collection

To obtain the maximum yield of organisms, blood should be collected immediately before the onset of chills. Since prediction of this event is rarely possible, it is generally recommended to draw blood for culture when the patient's temperature rises, as soon as possible after the onset of fever or chills or in connection with other symptoms that indicate sepsis (see Definitions). There is no evidence to support basing the time of collection on specific temperature thresholds (e.g. 39°C). It has also been recommended to draw blood cultures at arbitrary intervals (Strand and Shulman 1988), but others did not find an increase in sensitivity if blood cultures were obtained simultaneously, instead of spaced over time (Li et al. 1994). Intervals should be based on the patient's clinical condition, and should not result in delaying therapy in critically ill patients (O'Grady et al. 1998). Whenever possible, blood cultures should be obtained before antimicrobial chemotherapy is initiated, because ongoing antimicrobial chemotherapy significantly reduces the yield. If a patient is already receiving antimicrobials, blood cultures should be drawn towards the end of a dosing interval. If possible, antimicrobial therapy should be stopped and cultures should be obtained 24–48 h after the last dose was administered.

Collection site

Usually blood for culture is drawn from a peripheral vein, e.g. vena cubitalis. Contamination is more likely if the femoral vein or a vein in close proximity to an inflammation or skin infection site is used (Washington 1975). In neonates, special blood culture systems can be used to obtain blood from better accessible sites. Arterial blood does not offer any advantage with regard to detection of pathogens, not even for endocarditis or

fungemia (Tenney et al. 1982; Vaisanen et al. 1985). The reliability and diagnostic impact of blood cultures drawn through an intravascular catheter is controversial (Tonnesen et al. 1976; Bryant and Strand 1987). Contamination rates are usually higher and catheters may be colonized with organisms that do not necessarily invade the bloodstream. However, blood from this source, even via different lumens of the catheter, may be used in conjunction with peripheral venous samples to assess the presence of a catheter-related BSI. In this case quantitative blood cultures (lysis centrifugation method) or differential time to positivity when using a continuously monitoring blood culture system (CMBCS) can be used (Blot et al. 1999; Mermel et al. 2001; Rijnders et al. 2001; Gaur et al. 2003; Seifert et al. 2003a).

Volume

In adults, bacteremia is usually characterized by <1 bacteria per ml of blood (i.e. colony forming units (cfu)/ml) (Ilstrup and Washington 1983; Plorde et al. 1985; O'Hara et al. 2003). The volume of blood obtained for culture is therefore one of the most important variables influencing the diagnostic yield (Reller et al. 1982; Wilson et al. 1994). The diagnostic yield of a blood culture is directly related to the volume of blood obtained for culture (Hall et al. 1976; Tenney et al. 1982; Ilstrup and Washington 1983; Plorde et al. 1985) and increases by approximately 3–5 percent per ml blood taken (Hall et al. 1976; Tenney et al. 1982; Mermel and Maki 1993). In clinical practice, usually 10–20 ml of blood per culture is obtained and distributed evenly into an aerobic and an anaerobic culture bottle, leading to a final volume of 5–10 ml blood per bottle (Tenney et al. 1982). According to guidelines, 10 ml per culture are reasonable with an optimal volume being 20–30 ml per culture, depending on the number and type of bottle used (Washington and Ilstrup 1986; Dunne et al. 1997). The ratio between blood and culture media (blood to broth) should be 1:5–1:10, in order to neutralize the bactericidal activity of human serum (see below). For details on the optimal volume of blood per bottle, the instructions of the respective manufacturers should be consulted. Even though the diagnostic impact of the anaerobic vial is controversial (Sharp et al. 1991; Murray et al. 1992), the use of two vials ensures the culture of an adequate blood volume increasing the probability of recovery.

In pediatric patients a smaller volume (1–5 ml) is usually sufficient, because the concentration of microorganisms in these patients is higher (>100 cfu/ml blood) (Dietzmann et al. 1974; Szymczak et al. 1979; La et al. 1981; Reller et al. 1982). Even though less than 1 ml of blood may allow detection of microorganisms in infants if the concentration is high enough (Dietzmann et al. 1974; Neal et al. 1986), the diagnostic yield in these patients is also higher if a bigger blood volume is obtained (Szymczak et al. 1979; Isaacman et al. 1996; Kellogg et al. 2000). Recent studies showed that the detection rate in pediatric patients doubled if 6 ml of blood were obtained instead of 2 ml (Isaacman et al. 1996). Showing that low-level BSI does occur in children, some authors recommend obtaining 4–4.5 percent of a child's blood volume for culture (Kellogg et al. 2000). Specific 'pediatric' blood culture bottles contain a decreased volume of broth, and are supplemented with X and V factors and sodium-polyanetholesulfonate (SPS) to enhance detection of microorganisms. In these bottles, a decreased volume is necessary to maintain an optimal broth:blood ratio. However, data proving the necessity of using these bottles remain rare (O'Hara et al. 2003).

The protective covers of the vials should be removed close to inoculation. The membrane should be disinfected using sterile alcohol swabs. As with any disinfection, contact times should be observed and the membranes must be completely dry before inoculation. Based on the data of a meta-analysis, a new needle should be used to inoculate the vials in order to reduce contamination (Spitalnic et al. 1995). However, others have found no significant increase in contamination rates when a single-needle technique was used and have argued that the benefit of the reduced risk of needlestick injuries of the single-needle technique outweighs the increase in risk of contamination (Mylotte and Tayara 2000b). The atmosphere of aerobic vials used for automated blood culture processing in CMBCS is enriched with oxygen, which eliminates the need for transient venting after inoculation (Rohner et al. 1996).

Number of blood cultures

The detection rate increases with the number of blood cultures obtained. In patients with endocarditis, studies found a sensitivity of 80 percent if one blood culture was used, which increased to 88 and 99 percent if two or three independent cultures, respectively, were obtained over a 24 h period (Washington 1975; Weinstein et al. 1983b). Other studies in patients with BSI found 99 percent sensitivity if only two cultures were drawn (Weinstein et al. 1983b). Therefore, more than three blood cultures do not increase the diagnostic yield, but do increase costs and may cause iatrogenic anemia (Neu 1986). Also, the culture of only a single blood sample should be highly discouraged (Aronson and Bor 1987). There is currently no recommendation for an optimal time difference between the first and the second culture. In patients with suspected endocarditis, two to three blood cultures should be obtained within 24 h. In severely ill patients, it may be necessary to obtain two cultures (with separate venipunctures) in rapid succession in order to start antimicrobial therapy as soon as

possible (Smith-Elekes and Weinstein 1993). A recent study failed to show any benefit in yield of obtaining multiple samples, and recommended obtaining a total volume of 35–42 ml blood for six bottles at the same time (Lamy et al. 2002). However, for interpretation of results more than one separate culture (venipuncture) is needed. In neonates, drawing of a second culture is rarely possible. However, in infants or older children, two vials are mandatory, but the inoculation volume may be as low as 1 ml per vial (see Volume).

Media

Depending on the indication, the patient, and the suspected pathogen, the use of special culture media or a different number of bottles per blood culture may be useful. Commercial media that facilitate growth of almost any pathogen are readily available. Nutrient-rich broth in a variety of formulations can be used to culture microorganisms from the blood. These include brain–heart infusion (BHI) broth, tryptic-soy-broth (TSB), soybean casein digest broth, peptone broth, and Columbia media, which may be supplemented with hemin or NADH. Generally, one vial contains 50–100 ml of media and a 10 percent CO_2 atmosphere in the headspace. Therefore, vials can be used to culture aerobic, facultative, and anaerobic bacteria. An aerobic and an anaerobic bottle are usually obtained, i.e. one containing ambient atmosphere in the headspace, the other various amounts of CO_2. Due to the decrease of BSI caused by anaerobic bacteria over the past decades (Dorsher et al. 1991; Lombardi and Engleberg 1992; Murray et al. 1992; Dunne et al. 1997; Weinstein et al. 1997; Wisplinghoff et al. 2004), some authors have suggested that routine use of anaerobic bottles is not necessary, favoring two aerobic bottles to increase the volume of blood cultured (Murray et al. 1992; Morris et al. 1993; Sharp et al. 1993; Zaidi et al. 1995). However, recent surveys found anaerobes accounting for about 4 percent of BSI (Diekema et al. 2003) and anaerobic blood cultures enhance the isolation of other species, such as streptococci including *Streptococcus pneumoniae*, enterococci, and *Listeria monocytogenes* (Cockerill et al. 1997).

Inhibition of antimicrobial agents

Microbial growth in human blood is inhibited by a number of substances including antibodies, leukocytes, complement, lysozyme, and antimicrobial substances, which about one-third of patients already receive, when blood cultures are obtained (Weinstein et al. 1997). Blood clots also reduce the diagnostic yield. Virtually all commercially available blood culture bottles and media contain SPS (Wilson et al. 1994), an anticoagulant that inhibits lysozomal activity, complement, and phagocytosis, in addition to reducing blood clots (Traub and Kleber 1977; Washington and Ilstrup 1986; Chandrasekar and Brown 1994). Also, the 1:5 to 1:10 dilution of the blood enhances detection of bacteria by neutralizing the endogenous antibacterial activity of the human serum and diluting antimicrobial agents to subinhibitory concentrations. Aminoglycosides and polymyxins are also inhibited by SPS. Side effects of SPS include some inhibition of the growth of *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Gardnerella vaginalis*, *Peptostreptococcus anaerobius*, and *Moraxella catarrhalis* and a growth enhancement for gram-positive cocci while gram-negative rods are generally inhibited (Staneck and Vincent 1981; Edberg and Edberg 1983; Reimer and Reller 1985; Reimer et al. 1987). Others found that increasing concentrations of SPS increase the recovery of gram-negative bacteria (Chandrasekar and Brown 1994; Wilson et al. 1994). Despite these effects, no other anticoagulant to date is superior. Antimicrobial agents can also be neutralized by adding unspecific adsorbants such as antimicrobial removal device (ARD) (Peterson et al. 1983), antibiotic binding resins on glass beads (BACTEC) (BD, Sparks, MD), or activated charcoal and Fuller's earth (Ecosorb, BacT/ALERT, bioMérieux Inc., Durham, NC). Supplemented media have shown increased detection rates (Weinstein et al. 1995; Doern et al. 1997), but also increased the number of detected contaminants (Weinstein et al. 1995). Studies of the effects of the antimicrobial removal device have shown conflicting results (Appleman et al. 1982; Peterson et al. 1983; Doern 1994) and routine use is generally not recommended (Shafazand and Weinacker 2002).

Transport

Rapid transport of blood cultures to the microbiology laboratory is mandatory. Blood cultures used in CMBCS can be stored at room temperature if direct transport to the laboratory is not possible. Refrigeration of blood cultures should be avoided. In the laboratory, all blood cultures should be processed immediately. Incubation of blood cultures before transport to the microbiology laboratory is not needed with bottles used in CMBCS. If cultures have been incubated prior to arrival at the microbiology laboratory, Gram stains and blind subcultures of all bottles need to be performed before the cultures are processed in the CMBCS.

SAMPLE PROCESSING

In patients with BSI, the appropriateness of antimicrobial chemotherapy is correlated with survival (Ibrahim et al. 2000). The first notification of positive blood cultures has a high impact on the antimicrobial therapy (Schonheyder and Hojbjerg 1995). Samples should therefore be processed as fast as possible. Proces-

sing of blood cultures generally includes incubation, Gram staining, and subcultures. Manual processing has continuously decreased over the last decade and most laboratories now use automated blood culture systems. Several authors have compared different processing methods and systems. Table 3 compares commonly used blood culture methods.

Manual processing

All manual processing where aerosols could be generated, should be done under a protective hood, both to avoid contamination and to protect laboratory personnel. All blood cultures should be incubated for at least 6–18 h at 36 ± 1°C before processing. Agitation during incubation increases sensitivity and speed of detection (Hawkins et al. 1986; Weinstein et al. 1989; Prag et al. 1991). Afterwards, blind subcultures and microscopic examination of all aerobic cultures should be performed, using approximately 0.2 ml of broth, which should be removed under sterile precautions after gentle shaking. For microscopic examination, Gram or acridinorange stains can be performed. Gram stains are easier to perform, but may lack sensitivity. While acridinorange stains detected 10^4 cfu/ml, Gram stains only detected 10^5 cfu/ml (Seifert et al. 1997). If bacteria are seen, the respective anaerobic (or aerobic) bottle should also be subcultured. Blood-agar, chocolate-agar, anaerobic media, and some differential media (e.g. MacConkey) should be used for subculture of blood cultures and subsequently incubated at 36 ± 1°C in an aerobic atmosphere with 5–10 percent CO_2. Also if signs of turbidity, change of color, or gas production are detected, the respective culture bottle must be processed (i.e. subculture and Gram stain).

Blood cultures do not need to be routinely incubated for more than 7 days. Incubation periods are commonly extended if slow growing organisms or infective endocarditis are suspected, even though some authors noted that in the latter this practice rarely increases sensitivity (Washington 1994). If the cultures remain negative, Gram stains and blind subcultures of the aerobic bottle should be performed again at the end of the incubation period. Blind subcultures of anaerobic bottles do not increase diagnostic yield (Dunne et al. 1997). For special processing requirements, see also individual pathogens.

Automated processing

The first automated blood culture system, BACTEC 460 (Becton Dickinson), was introduced in the 1970s. The use of automated blood culture systems rapidly increased after the introduction of continuous monitoring blood culture systems in the early 1990s. As the earliest systems, most CMBCSs are based on the detection of CO_2, which is produced as microorganisms grow and utilize carbohydrate substrates. While the BACTEC 460 used ^{14}C for detection, the newer instruments of the BACTEC 9000 series use a fluorescence-sensing mechanism. Detection criteria are a linear increase in fluorescence intensity and a change in the increase rate of fluorescence intensity. The BacT/ALERT 3D (bioMérieux) which is the updated version of the BacT/ALERT uses a colorimetric CO_2 sensor system. With emitting and sensing diodes in the incubator units, growth is detected if reflection exceeds an arbitrary threshold, a linear increase or a change in the increase rate are detected. In contrast, the ESP blood culture system (Trek Diagnostic Systems, Inc.) monitors the pressure changes within the bottles' headspace, which changes with the consumption or production of gases (oxygen, hydrogen, nitrogen, CO_2) by growing microorganisms. In all systems cultures are monitored at intervals between 10 and 24 min, 24 h per day, shortening time to detection by 1–1.5 days (Wilson et al. 1992; Morello et al. 1994; Reimer et al. 1997). A 5-day incubation in a CMBCS is usually sufficient to detect most pathogens (Masterson and McGowan 1988; Hardy et al. 1992; Wilson et al. 1993) and even periods of 4 (Dorsher et al. 1991; Johnson et al. 2000) or 3 (Han and Truant 1999; Bourbeau and Pohlman 2001) days have been suggested.

As in manual processing, Gram stains and subcultures must be performed if growth of microorganisms is detected in a culture. Of note, some systems can only detect an increase in CO_2 production, and may not detect a positive culture if the bacterial growth has already entered the static phase. Therefore, if the blood cultures have been incubated previously or obtained more than 24 h prior to processing, it is recommended that Gram stain and blind subculture of both bottles be performed before the culture vials are placed into the system. Blind subcultures of aerobic or anaerobic bottles at the end of

the incubation period do not increase the diagnostic yield (Dunne et al. 1997).

Quantitative blood cultures

The lysis centrifugation system (ISOLATOR, Du Pont) is the only commercial quantitative blood culture system. Processing of cultures is intensive in both time and labor and usually not used for routine diagnostic purposes. Vials contain saponin, EDTA, and SPS and must be subcultured on aerobic and anaerobic media after centrifugation. Samples should be processed within 8–10 h after collection. For detailed procedures the reader is referred to the instructions of the respective manufacturer. However, some advantages of the lysis centrifugation method over qualitative blood cultures have been reported: diagnosis is usually faster than with conventional blood cultures. Also diagnostic yield of the ISOLATOR system is higher in some pathogens such as fungi (see Table 3).

INTERPRETATION OF RESULTS

Interpretation of the clinical significance of positive and negative blood culture results can be problematic. Misinterpretation can lead to antimicrobial therapy which is expensive and may lead to adverse events in the patient. Recovery of *Staphylococcus aureus*, *S. pneumoniae*, *Escherichia coli* and other Enterobacteriaceae, *Pseudomonas aeruginosa* and *Candida albicans* almost always represents true infection. Other microorganisms including *Corynebacterium* species, *Bacillus* species, and *Propionibacterium* species only rarely cause true BSI (Weinstein et al. 1997). The majority of coagulase-negative staphylococcal isolates also represent contamination rather than true infection. To aid interpretation a number of approaches have been suggested. In addition to the identity of the microorganism, the presence of the same organism in more than one independently obtained culture, or the isolation of the same organism from another usually sterile body site may provide valuable aid for interpretation. Correlation of laboratory findings with the clinical status of the patient is mandatory. Generally, clinically significant BSI is likely if two or more separate blood cultures grow the same organism (Weinstein 1996; Kim et al. 2000; McDonald et al. 2001). Interpretation of CoNS isolated from blood cultures is particularly difficult, since 12–15 percent of CoNS bloodstream isolates are the causative pathogens of clinical significant BSI (Weinstein et al. 1997). While in this instance the number of positive cultures in a set is not a reliable criterion (Peacock et al. 1995; McDonald et al. 2001), the number of positive cultures relative to the number of obtained cultures appears to be useful (Peacock et al. 1995; Weinstein et al. 1983b; Weinstein et al. 1997).

PATHOGENS

Almost any pathogen can be isolated from the bloodstream as a causative agent of clinically significant bacteremia, fungemia or BSI, especially in immunocompromised patients. In addition, in patients with a corresponding history (e.g. travel), parasitic and tropical diseases, which may require a different diagnostic approach should also be considered.

The spectrum of pathogens has changed considerably over the last decades (Figure 1). In recent studies, about 13 percent of all episodes were polymicrobial, 60–65 percent were caused by gram-positive and 25–31 percent by gram-negative organisms. Fungi, mainly *Candida* species, were isolated from 7–10 percent of episodes. Anaerobic bacteria accounted for about 1 percent of BSI (Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004). The most common pathogens isolated from BSI are listed in Table 4. Proportions of individual organisms vary with age, gender, underlying conditions, and clinical service.

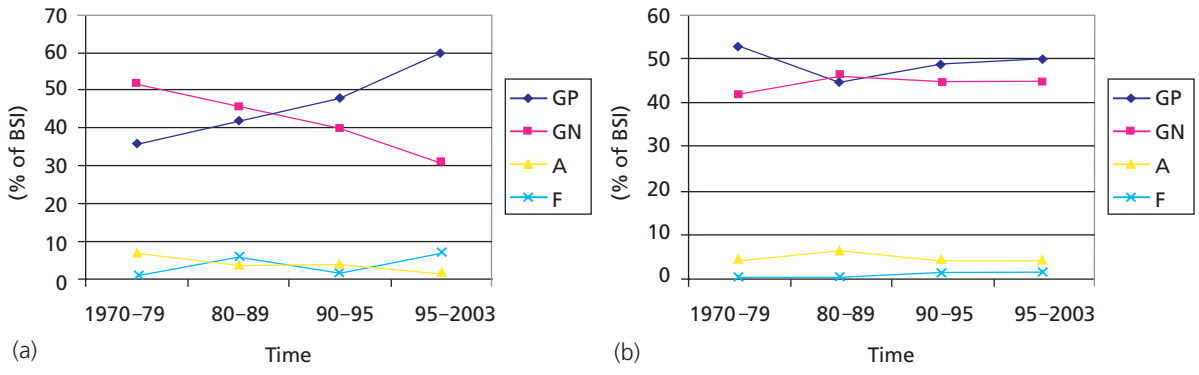

Figure 1 (a) *Trends in pathogens causing nosocomial BSI (data from Eykyn 1998; Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004).* **(b)** *Trends in pathogens causing community-acquired BSI. GRAM-POSITIVE ORGANISMS

In the 1980s, gram-positive organisms re-emerged as the leading pathogenic causes of nosocomial bloodstream infections (Figure 1). Today, gram-positive organisms account for about 65 percent of BSI and the three leading pathogens are gram-positive (Table 4). Most gram-positive bacteria causing BSI belong to the genus *Staphylococcus* or *Streptococcus*/*Enterococcus* (Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004).

Staphylococcus aureus

S. aureus is a major cause of morbidity and mortality. Localized infections have a tendency to spread to the surrounding tissue or frequently via the bloodstream to distant sites. Commonly isolated from patients with both community-acquired and nosocomial BSI, *S. aureus* is the second most common cause of nosocomial BSI, accounting for 20 percent of these infections with an incidence of about 1 per 1 000 hospital admissions (Wisplinghoff et al. 2004). Incidence varies with age ranging from about 10 percent in patients under the age of 1 year to about 24 percent in patients over the age of 65 years (Diekema et al. 2002; Wisplinghoff et al. 2004). *S. aureus* BSI usually originates from a localized infection, an intravascular catheter or a contaminated syringe (e.g. in IV drug users). For example, a high correlation has been reported between *S. aureus* BSI and mediastinitis in patients with coronary artery bypass graft (CABG) (Fowler et al. 2003) and isolation of *S. aureus* even from a single blood culture should prompt the search for a primary focus of infection. Clinical manifestations range from benign transient bacteremia with a single episode of fever and chills to fulminant septic shock. Crude mortality associated with nosocomial *S. aureus* BSI ranges from about 18 to 34 percent; in patients with community-acquired *S. aureus* BSI, mortality rates ranging between 12 percent in unselected patient populations and 58 percent in critically ill patients have been reported (Diekema et al. 2003; Valles et al. 2003; Wisplinghoff et al. 2004).

Methicillin resistance, first detected in the 1960s (Barber 1961), emerged as a major clinical and epidemiological problem in hospitals in the 1980s. In hospitals in the United States, the proportion of isolates of methicillin-resistant *S. aureus* (MRSA) have increased from 2.4 percent in 1975 to up to 55 percent in recent years (NNIS 2003). Whether resistance to methicillin is related to transmission or virulence is controversial. Several clinical studies could not identify significant differences in the mortality rate for patients with infections due to methicillin-resistant strains and that for patients with methicillin-susceptible *S. aureus* (MSSA) strains, after correcting for various confounding variables (Hershow et al. 1992; Mylotte et al. 1996; Pujol et al. 1996; Harbarth et al. 1998; Wisplinghoff et al. 2001). In contrast, other studies have suggested that outcome of methicillin-resistant *S. aureus* BSI is significantly worse and that methicillin resistance is an independent predictor of adverse outcome of patients with *S. aureus* infections (Rello et al. 1994; Romero-Vivas et al. 1995; Blot et al. 1998; Conterno et al. 1998; Blot et al. 2002b; Cosgrove et al. 2003). Even though MRSA has been a nosocomial pathogen, there are an increasing number of reports of MRSA BSI in patients with little or no association to the healthcare system (Frank et al. 1999; Fergie and Purcell 2001; Groom et al. 2001; Naimi et al. 2001; Wu et al. 2002; Aires and De Lencastre 2003; Baggett et al. 2003; CDC 2003; Johnson et al. 2003; Said-Salim et al. 2003), suggesting the emergence of true community-acquired MRSA. In recent years there have been a number of

reports of glycopeptide or vancomycin-intermediate *S. aureus* isolates (Rotun et al. 1999; Smith et al. 1999; Wong et al. 2000; Fridkin 2001; Hageman et al. 2001; Fridkin et al. 2003; Naimi et al. 2003) and recently, a *S. aureus* isolate with high-level vancomycin-resistance conferred by the *vanA* gene has been recovered from a catheter tip culture (Johnson et al. 2003).

Small colony variants (SCV), a naturally occurring subpopulation of *S. aureus* have also been identified as a cause of BSI (Seifert et al. 2003b). *S. aureus* SCVs have been implicated in persistent and recurrent infections that give a poor clinical and bacteriological response to standard antimicrobial therapy in patients with BSI, chronic osteomyelitis, cystic fibrosis, and AIDS particularly after prolonged exposure to antibiotics (von Eiff et al. 1997; Kahl et al. 1998; Proctor et al. 1998; Seifert et al. 1999, 2003b). These phenotypic variants are characterized by their fastidious growth and atypical colony morphology on routine media, making recovery as well as correct identification difficult for microbiological laboratories.

Delay of therapy can have deleterious effects on clinical outcomes in patients with *S. aureus* BSI, and appropriate therapy should be initiated without delay (Lodise et al. 2003).

Coagulase-negative staphylococci

BSI caused by Coagulase-negative staphylococci (CoNS) is mostly nosocomial, but CoNS have also been isolated from about 8 percent of patients with community-acquired BSI (Diekema et al. 2003). According to several surveys, CoNS are the most prevalent pathogen isolated from the blood accounting for 15–30 percent of blood culture isolates (Moser et al. 1998; Edmond et al. 1999; NNIS 2000; Diekema et al. 2003; Wisplinghoff et al. 2004). This difference is mostly due to the definitions used in different studies, with lower incidences being reported if only cases were included where CoNS were isolated from two or more separate blood cultures. The fact that CoNS also constitute a major part of the normal microflora makes interpretation of positive blood culture results difficult and if possible detection should be confirmed by more than one blood culture. Although several approaches have been suggested to aid interpretation, this issue remains controversial (see Interpretation of results). *S. epidermidis*, the most frequently isolated species among CoNS has been implicated in a variety of infections, including BSI (Rupp and Archer 1994), mostly associated with intravascular catheters and other prosthetic devices. *S. haemolyticus*, the second most commonly isolated species among CoNS has also been associated with BSI and other infections (Kloos and Bannerman 1994; Rupp and Archer 1994). A variety of other CoNS have also been implicated in BSI, including *S. capitis*, *S. hominis*, *S. lugdunensis*, *S. saprophyticus*, *S. schleiferi*, *S. simulans*, and *S. warneri*. The proportion of CoNS among blood culture isolates seems to decrease with increasing age (Diekema et al. 2002; Wisplinghoff et al. 2004). Crude mortality in patients with CoNS BSI ranges from 14 to 31 percent (Diekema et al. 2003; Wisplinghoff et al. 2004).

Enterococcus species

Enterococcus species are the third most common cause of BSI in the United States (Murray 1990; Schaberg et al. 1991; Moellering 1992; Wisplinghoff et al. 2004), accounting for about 9 percent of nosocomial BSI (Edmond et al. 1999; Wisplinghoff et al. 2004). Enterococcal BSI is mainly nosocomial, and community-acquired BSI due to enterococci should always raise the suspicion of endocarditis. *Enterococcus faecalis* is the most prevalent species, accounting for 80–90 percent of clinical isolates, followed by *E. faecium* (5–10 percent of isolates) (Facklam and Collins 1989; Gordon et al. 1992; Buschelman et al. 1993; Stern et al. 1994). Other enterococci that are rarely isolated from blood include *E. casseliflavus*, *E. gallinarum*, and *E. raffinosus*. As with other gram-positive pathogens, the incidence of nosocomial BSI due to enterococci has been increasing over the past decades (Graninger and Ragette 1992; Maki and Agger 1988; Edmond et al. 1999; Wisplinghoff et al. 2004) and some studies found *Enterococcus* species particularly involved in polymicrobial BSI (Maki and Agger 1988). Primary BSIs are generally seen in highly compromised or immunosuppressed patients and may be due to inapparent bacterial translocation from a gastrointestinal source (Shlaes et al. 1981b; Graninger and Ragette 1992; Linden et al. 1996) or intravascular catheters. Secondary BSI is more frequently seen than primary BSI and usually derives from the urinary or gastrointestinal tract, or from wound infections (Shlaes et al. 1981b; Maki and Agger 1988; Graninger and Ragette 1992). Crude mortality of enterococcal BSI ranges from 34 percent in unselected patients populations to 43 percent in ICU patients (Wisplinghoff et al. 2004). Complications such as septic shock, metastatic infection (except endocarditis, see below) or adverse outcome are rare in monomicrobial enterococcal BSI (Maki and Agger 1988). *E. faecalis* isolates are mostly susceptible to ampicillin and vancomycin, while *E. faecium* isolates are usually susceptible to vancomycin only. Vancomycin-resistant strains emerged in the late 1980s in Europe and have become an increasing nosocomial problem in the United States. Several authors have reported that vancomycin-resistant enterococcal BSI contributes significantly to excess mortality and economic loss (Bhavnani et al. 2000; Lodise et al. 2003; Song et al. 2003) and that early, effective antimicrobial therapy is associated with a significant improvement in survival (Vergis et al. 2001).

Streptococcus pneumoniae

In *S. pneumoniae*, BSI is usually community-acquired and secondary to pneumonia, meningitis or otitis media (Raz et al. 1997). In a recent study about 10 percent of pneumococcal BSI were nosocomial (Canet et al. 2002). The overall incidence of invasive pneumococcal disease is about 15 per 100 000 person-years (Fedson et al. 1998), even though it may be up to ten-fold higher in certain risk populations (Davidson et al. 1994; Torzillo et al. 1995). Neonates and children under the age of 2 years are more likely to develop pneumococcal BSI, as are elderly people over the age of 65 years (Burman et al. 1985; Breiman et al. 1990) with incidences of 160 and 70 per 100 000 person-years, respectively compared to 5 per 100 000 in young adults (Breiman et al. 1990). Incidence of pneumococcal BSI is seasonal with a peak in the cold season (Kim et al. 1996). Meningitis generally occurs in a relatively small number of cases of community-acquired pneumococcal BSI (Gruer et al. 1984), but has been reported in up to 17 percent of patients with BSI by Kuikka et al. (1992). A variety of factors have been identified that predispose to invasive pneumococcal disease, such as immunosuppresion, alcoholism, and chronic lung disease (Burman et al. 1985; Fang et al. 1990; Rahav et al. 1997; Watanakunakorn and Bailey 1997). Severe cases of BSI due to *S. pneumoniae*, often associated with a fatal outcome, occur in children under the age of 2 years or who are physically or functionally asplenic, such as children with sickle cell disease in whom a 100-fold higher incidence of pneumococcal BSI has been reported (Wara 1981; Wong et al. 1992).

While pneumonia and meningitis are the most frequent entities associated with pneumococcal BSI, other manifestations include spontaneous bacterial peritonitis (Wilcox and Dismukes 1987; Gorensek et al. 1988; Shaked and Samra 1988), endo- or pericarditis (Powderly et al. 1986), epidural and brain abscesses, and soft tissue infections (Peters et al. 1989; DiNubile et al. 1991; Grigoriadis and Gold 1997).

Rates of penicillin resistance among peneumococci isolated from the blood increased over the past decade. Recent studies reported a percentage of penicillin-resistant isolates of 25–60 percent with a high degree of variation between individual countries, cities, or hospitals (Doern et al. 1998; Yu et al. 2003). Recent studies in patients with pneumococcal BSI found no correlation between penicillin resistance and outcome (Maugein et al. 2003; Yu et al. 2003).

Other gram-positive organisms

In otherwise healthy adults other gram-positive organisms rarely cause BSI. Among *Streptococcus* species other than *S. pneumoniae*, BSI can also be due to viridans group streptococci as well as serogroups A (e.g. *S. pyogenes*), B (e.g. *S. agalactiae*), D (e.g. enterococci), and G (Facklam 2002). Viridans group streptococci, part of the normal human commensal flora, have been associated with subacute endocarditis (see below), especially *S. gordonii*, *S. mitis*, *S. oralis*, and *S. sanguis* (Douglas et al. 1993; Bouvet et al. 1994). These species have also emerged as important pathogens causing bacteremia and sepsis in neutropenic cancer patients (Awada et al. 1992; Bochud et al. 1994a; Carratala et al. 1995; Richard et al. 1995; Gonzalez-Barca et al. 1996; Bilgrami et al. 1998). Clinical manifestations of viridans group streptococcal bacteremia in these patients may include fever, hypotension, shock, pneumonia, and adult respiratory distress syndrome, with a mortality rate ranging from 6 to 30 percent (Bochud et al. 1997). Serious complications of viridans group streptococcal BSI associated with a high mortality rate occur mainly in patients receiving high-dose antineoplasmatic chemotherapy who develop severe oral mucositis (Marron et al. 2000). The increased frequency of these infections has been attributed to several factors, including high-dose chemotherapy with cytosine arabinoside, oropharyngeal mucositis, and prophylactic therapy with cotrimoxazole or a fluoroquinolone (Elting et al. 1992; Bochud et al. 1994a; Richard et al. 1995). Oral and gastrointestinal mucosal lesions and intravascular catheters have been suggested as the most frequent portals of entry (Elting et al. 1992; Bochud et al. 1994b; Richard et al. 1995; Gonzalez-Barca et al. 1996). In the past, viridans group streptococci were considered to be uniformly susceptible to beta-lactam antimicrobial agents, macrolides, and tetracyclines. However, the emergence of strains resistant to beta-lactams and other antibiotics is a cause of concern and could compromise currently used prophylactic and therapeutic antibiotic regimens (Carratala et al. 1995; Doern et al. 1996; Pfaller et al. 1997; Wisplinghoff et al. 1999). Viridans group streptococcal BSI in both immunocompetent and immunocompromised patients is usually considered to be of endogenous origin.

Streptococci of the *S. anginosus* group (i.e. *S. anginosus*, *S. constellatus*, and *S. intermedius*; previously known as the *S. milleri* group) have been associated with a variety of invasive pyogenic infections. Most episodes of BSI are associated with an identifiable focus (Shlaes et al. 1981a; Kambal 1987; Gossling 1988; Jacobs et al. 1995; Casariego et al. 1996; Salavert et al. 1996; Bancescu et al. 1997), or have been reported in patients with neutropenia or underlying malignancies (Cohen et al. 1983; Awada et al. 1992; Pfaller et al. 1997), but these organisms were also described in neonates and pediatric patients (Hamoudi et al. 1990; Weisman et al. 1990; Raymond et al. 1995). Other clinical features include pulmonary infections, septic arthritis, osteomyelitis, and brain abscesses (Houston et al. 1980; Shlaes et al. 1981a; Brook et al. 1988; Molina et al. 1991; Wong et al. 1995; Jerng et al. 1997).

BSI is relatively uncommon (Weinstein et al. 1983b) in *S. pyogenes* infections. During the 1990s, an increase in frequency and severity of invasive infections due to group A streptococci has been reported (Martin and Hoiby 1990; Demers et al. 1993; Hoge et al. 1993). Patients were predominantly otherwise healthy adults and there has been an association with IV drug abuse (Barg et al. 1985; Craven et al. 1986; Lentnek et al. 1990). Other risk factors include immunosuppression and underlying malignancies, diabetes mellitus, and vascular disease. The clinical course is often fulminant and mortality ranges from 27 to 38 percent with an association of M types 1 and 3 with a more severe clinical course (Francis and Warren 1988; Ispahani et al. 1988; Stevens et al. 1989; Dan et al. 1990; Bucher et al. 1992; Johnson et al. 1992; Demers et al. 1993; Hoge et al. 1993; Martin and Single 1993).

Clinical manifestations of *S. agalactiae* BSI include early and late onset infection in neonates and primary and secondary BSI in adults. BSI is the most common clinical feature of early onset disease (occurring within the first 6 days) which is associated with maternal obstetric complications and infants born at less than 37 weeks. Symptoms are mainly nonspecific and do not allow distinction between infants with and without accompanying meningitis (Baker 1976; Franciosi et al. 1973; Chin and Fitzhardinge 1985). Mortality ranges from 5 to 10 percent and is inversely correlated to birth weight (Yagupsky et al. 1991; Schuchat 1998; Hyde et al. 2002). Occult BSI and meningitis are the most common manifestations of late onset infection (between 7 days and 3 months of age) and mortality is low (Schuchat 1998; Schuchat et al. 1990; Yagupsky et al. 1991; Hyde et al. 2002). In adults, the incidence of group B streptococcal BSI is 0.2 per 1 000 hospital admissions (Opal et al. 1988). About 68 percent of cases are unrelated to pregnancy and there is a predominance of the elderly (Lerner et al. 1977; Gallagher and Watanakunakorn 1985; Verghese et al. 1986; Opal et al. 1988; Schwartz et al. 1991). Predisposing conditions include diabetes, liver disease, neurologic impairment, underlying malignancy, renal failure, cardiovascular disease, and heart failure (Lerner et al. 1977; Gallagher and Watanakunakorn 1985; Verghese et al. 1986; Opal et al. 1988; Schwartz et al. 1991; Farley et al. 1993). Primary BSI accounts for 20–40 percent of cases and is associated with fatal outcome in about 50 percent of cases (Lerner et al. 1977; Opal et al. 1988; Colford et al., 1995; Munoz et al. 1997).

Listeria species, short gram-positive rods, are widely distributed in the environment. *Listeria monocytogenes* is usually seen as a cause of community-acquired BSI and meningitis. Immunocompromised patients including elderly patients are particularly susceptible (Nieman and Lorber 1980; Schuchat et al. 1991). *L. monocytogenes* can cross the placenta, therefore in pregnant woman *L. monocytogenes* BSI can be complicated by placentitis or amnionitis leading to infection of the fetus, abortion or premature birth (Bille et al. 2003). Other clinical manifestations are rare and include cutaneous listeriosis, endocarditis, osteomyelitis, and intraabdominal abscesses (McLauchlin and Low 1994). Early diagnosis is based on maternal blood cultures growing *L. monocytogenes*. Immunoassays based on monoclonal antibodies are also available for rapid detection of *Listeria* species from the blood. Also, polymerase chain reaction (PCR) assays are highly sensitive and specific and can be particularly useful if the patient was receiving antimicrobial therapy prior to culture (Bille et al. 2003).

GRAM-NEGATIVE ORGANISMS

During the 1960s and 1970s, gram-negative organisms were the most frequent blood culture isolates. Today they are isolated from about 30 percent of BSI.

Escherichia coli and other Enterobacteriaceae

Enterobacteriaceae are important causes of both community-acquired and nosocomial infections including BSI. The Enterobacteriaceae combined account for about 17 percent of all BSI (Diekema et al. 1999; Edmond et al. 1999; Wisplinghoff et al. 2004), making them the second most common cause of BSI after CoNS. Besides their involvement in almost any kind of infection, Enterobacteriaceae are an important part of the normal intestinal flora. *E. coli*, the most commonly isolated pathogen in community-acquired BSI (Diekema et al. 2003), accounts for about 7–11 percent of nosocomial BSI to date (Pittet and Wenzel 1995; Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004). Community-acquired BSI due to *E. coli* is usually secondary to urinary tract infection and, less frequently, infection of the gastrointestinal tract (Eisenstein and Zaleznik 2000). *E. coli* strains causing BSI are phenotypically similar to those isolated from urinary tract infections (Johnson et al. 1997; Johnson et al. 2002). In patients with nosocomial BSI, primary sources of infection include IV catheters, the gastrointestinal, respiratory, and urinary tract. A portal of entry is usually absent in patients undergoing chemotherapy, where impairment of the intestinal mucosa may lead to bacterial translocation as a cause of BSI. Metastatic manifestations associated with BSI include septic arthritis, osteomyelitis, septic thrombophlebitis, abscesses in brain and liver, among others (Goldenberg et al. 1974; Saksouk and Salti 1977; Faraawi and Fong 1988; Farstad et al. 2003; Levy et al. 2003b).

Klebsiella species are a frequent cause of gram-negative nosocomial BSI, accounting for about 10 percent of community-acquired BSI and about 6 percent of nosocomial BSI (Diekema et al. 1999; Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004). Similar to *E. coli*, BSI usually originates from a distant site, most

commonly from the urinary tract, followed by the lower respiratory tract, bile duct, and wound infections (Eisenstein and Zaleznik 2000). In patients with nosocomial BSI, crude mortality rates of 25 percent have been reported (Diekema et al. 1999; Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004). A recent survey found no difference in mortality between ICU patients with BSI caused by *Klebsiella* spp. and matched controls after adjusting for severity of underlying disease and acute illness (Blot et al. 2002a).

Enterobacter and *Serratia* species are less frequent causes of nosocomial BSI, accounting for 3 and 4 percent of BSI in recent studies, respectively (Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004). Both are opportunistic pathogens and infections occur in patients with numerous predisposing conditions including immunosuppression, intravascular, intraperitoneal, or urinary catheters or following invasive procedures (Rudnick et al. 1996; Fok et al. 1998; Verghese et al. 1998; Eisenstein and Zaleznik 2000; Choi et al. 2002; Ostrowsky et al. 2002). *Serratia* species have also been associated with bacteremic infections in IV drug users, particularly endocarditis (see Infective endocarditis) (Wyler et al. 1975; Ashby 1976; Mills and Drew 1976). A recent study found that after adjustment for severity of underlying disease and acute illness and in the presence of fast and appropriate antibiotic therapy, *Enterobacter* BSI does not seem to adversely affect outcome in ICU patients (Blot et al. 2003b).

Non-typhoid *Salmonella* species usually cause intestinal infections and have been described as etiological agents of community-acquired BSI in both immunocompromised and previously healthy patients. Overall, BSI occurs in 1–4 percent of patients with gastroenteritis and can be caused by any *Salmonella* serotype. Frequencies are higher in patients with severe underlying conditions, immunosuppression, as well as in neonates and in elderly people (Han et al. 1967; Neves et al. 1971; Wolfe et al. 1971; Celum et al. 1987; Sperber and Schleupner 1987; Wheat et al. 1987; Levine et al. 1991). These patients also have a higher risk for severe invasive disease and extraintestinal manifestations including osteomyelitis, septic arthritis, meningitis, and endocarditis (Warren 1970; Wilson and Feldman 1981; Alvarez-Elcoro et al. 1984; Cohen et al. 1987; Stein et al. 1993; Huang 1996; Huang and Chuang 1997). In children, prolonged fever and infection with specific *Salmonella* serotypes is associated with BSI (Yang et al. 2002). Patients with BSI due to non-typhoid *Salmonella* species frequently have persistent bacteremia at follow-up regardless of the initial antibiotic treatment (Zaidi et al. 1999). *Salmonella typhi* is the etiologic agent of typhoid fever, a serious systemic infection, which is mostly seen in Third World countries. Patients usually suffer from continuous high fever and headache, without diarrhea. Typhoid fever has a generally more benign course in pediatric patients (Mermin et al. 1998). Typhoid fever is now rarely seen in the United States and Europe, and >70 percent of cases are travel-related (Mermin et al. 1998; Mead et al. 1999; Ackers et al. 2000).

Pseudomonas aeruginosa

P. aeruginosa is associated with a wide variety of infections, contributing significantly to morbidity and mortality of hospitalized patients. BSI is mainly nosocomial and usually affects patients with underlying clinical conditions such as malignancies, cardiac, or pulmonary diseases, renal failure or diabetes (El Amari et al. 2001). *P. aeruginosa* accounts for between 4 and 7 percent of nosocomial BSI, but for up to 31 percent of BSI in patients with underlying malignancies (Maschmeyer and Braveny 2000; Diekema et al. 2003; Wisplinghoff et al. 2004). Among gram-negatives, *P. aeruginosa* was the third most commonly isolated pathogen in recent surveys in North America (Weinstein et al. 1997; Diekema et al. 1999; Edmond et al. 1999; Wisplinghoff et al. 2004). The crude mortality of monomicrobial nosocomial *P. aeruginosa* BSI was between 28 and 48 percent in recent studies (Edmond et al. 1999; Diekema et al. 2003; Wisplinghoff et al. 2004). In patients with underlying malignancies crude mortality associated with *P. aeruginosa* BSI varied from 5 to 50 percent. *P. aeruginosa* BSI in IV drug users is relatively common and usually associated with endocarditis (see Infective endocarditis) (Komshian et al. 1990). Nosocomial pneumonia due to *P. aeruginosa* is often associated with BSI in neutropenic patients receiving chemotherapy as well as in adult or pediatric patients with AIDS (Iannini et al. 1974; Kielhofner et al. 1992; Flores et al. 1993). The prognosis of *P. aeruginosa* BSI secondary to nosocomial pneumonia is poor, and a fulminant progression to septic shock and death occurring within 3–4 days after the onset of pulmonary symptoms (Kang et al. 2003) is possible. Resistance of *P. aeruginosa* isolated from the blood is usually high, and therapy should be always based on susceptibility testing.

Acinetobacter baumannii

Acinetobacter species are a heterogenous group of organisms that have emerged as significant nosocomial pathogens mainly affecting patients with impaired host defenses in the intensive care unit setting. Members of the genus *Acinetobacter*, particularly *A. baumannii*, are implicated in a wide spectrum of infections, including nosocomial BSI, nosocomial pneumonia, secondary meningitis, skin and soft tissue infections, and urinary tract infections (Bergogne-Berezin and Towner 1996). The characteristics of *Acinetobacter* BSI have been described by researchers from various parts of the world (Tilley and Roberts 1994; Seifert et al. 1995; Cisneros et al. 1996; Ng et al. 1996; Siau et al. 1999; Wisplinghoff

et al. 2000). Since *Acinetobacter* species are ubiquitous organisms and most species represent contaminants rather than true pathogens, species identification of all BSI isolates should be attempted. While BSI rates as high as 8.4 percent have been reported for *Acinetobacter* species (Seifert et al. 1995), *A. baumannii* accounted for about 1–2 percent of BSI in recent studies (Edmond et al. 1999; Wisplinghoff et al. 2000, 2004), still being among the ten most prevalent causes of BSI. The crude mortality of *A. baumannii* BSI may be as high as 52 percent (Beck-Sague et al. 1990; Seifert et al. 1995; Cisneros et al. 1996; Cisneros and Rodriguez-Bano 2002), but was 34 percent in nosocomial BSI in unselected patient populations (Wisplinghoff et al. 2004). Others reported that *A. baumannii* BSI is not associated with a significantly increased mortality rate in critically ill patients (Blot et al. 2003a). Nosocomial BSI is often catheter-related or secondary to respiratory or urinary tract infections, as well as wound infections, particularly in burn patients. *Acinetobacter* species other than *A. baumannii* may also be associated with catheter-related BSI, but the clinical course in these cases tends to be less severe (Seifert et al. 1994).

Other gram-negative pathogens

Since the implementation of vaccination the number of invasive *Haemophilus influenzae* infections in the United States and Europe has decreased to below 100 cases per annum (Adams et al. 1993; CDC 1999). Systemic infection due to *H. influenzae* is usually community acquired. Virtually all invasive diseases – usually meningitis and BSI associated with acute epiglottitis – are caused by *H. influenzae* serotype b, which remains highly prevalent in unvaccinated children. Invasive disease due to other serotypes is rare, but has been reported for serotype f, mainly in immunocompromised patients (Gatti et al. 2004). All commercial blood culture media have a high recovery rate of *Haemophilus* species. For primary recovery, X- and V-factor enrichment of culture media is required.

Neisseria species

BSI due to *Neisseria* species is usually community acquired. Clinical manifestation of infections due to *N. meningitidis* may range from benign transient bacteremia to fulminant disease with high mortality (Apicella 2000). Transient, intermittent or persistent oro- or nasopharyngeal carriage of *N. meningitidis* has been reported in between 8 and 20 percent of healthy individuals (Ala'Aldeen et al. 2000). BSI due to *N. meningitidis* may be associated with meningitis, but transient bacteremia and severe sepsis have also been described without evidence of meningitis. Clinical presentation includes a maculopapular rash that becomes petechial and may be seen in 50 to 60 percent of patients. In severe sepsis, systemic coagulopathy may lead to ecchymotic, hemorrhagic, or necrotic areas. Purpura fulminans with extensive tissue damage is seen in 10 percent of patients. Septic shock can be the most prevalent symptom in patients with acute meningococcal BSI, but also in patients with meningitis (Apicella 2000; van Deuren et al. 2000). Mortality of meningococcal BSI associated with meningitis is usually between 7 and 10 percent, but can be as high as 30 percent (Dominguez et al. 2004). *N. meningitidis* has also been associated with chronic BSI, usually without meningitis (Apicella 2000). The clinical presentation includes fever, headache, leukocytosis, and arthritis.

Gonorrhea is still prevalent with highest incidences in sexually active teenagers between the ages of 15 and 24 (Sparling and Hansfield 2000). BSI due to *N. gonorrhoeae*, also referred to as disseminated gonococcal infection (DGI) occurs in 0.5–3 percent of cases (Hook and Hansfield 1999; Sparling and Hansfield 2000). Risk factors include female gender (especially during menstruation or the third trimester of pregnancy) and certain complement deficiencies (C7, C8, C9) (Ellison et al. 1987). Complications include gonococcal arthritis (in 30–40 percent of DGI) and rarely meningitis or endocarditis (Hook and Hansfield 1999; Sparling and Hansfield 2000).

FUNGI

Blood cultures are an important tool in the diagnosis of disseminated fungal infections (Weinstein et al. 1983b; Ellis 1991; Geha and Roberts 1994). All CMBCSs provide adequate detection of BSI due to yeasts (Mattia 1993; Prevost-Smith and Hutton 1994; McDonald et al. 2001). However, the lysis centrifugation system appears to be the most sensitive method for the detection of filamentous fungi as well as *Histoplasma capsulatum*, and other dimorphic fungi (Guerra-Romero et al. 1987; Graybill et al. 1990; Lyon and Woods 1995). When fungal BSI or disseminated fungal infection is suspected, maximum blood volumes should be collected multiple times and the use of special media should be considered.

Candida species, particularly *C. albicans*, are frequently isolated from the bloodstream, accounting for up to 10 percent of all nosocomial blood culture isolates. Data on the incidence of *Candida* BSI is controversial. A recent NNIS study (Trick et al. 2002) showed significant decreases in BSI due to *Candida* species and *C. albicans*, and reported a significant increase in BSI due to *C. glabrata* in ICUs between 1989 and 1999. Others, studying about 24 000 cases of nosocomial BSI from the United States, found a significant increase in the proportion of *Candida* species isolated from blood cultures between 1995 and 2002. In the same study, there was an increase in *C. albicans* and *C. parapsilosis* BSI, whereas

BSI caused by *C. tropicalis* and *C. glabrata* decreased (Wisplinghoff et al. 2004). Candida BSI is usually associated with long-term TPN and is most frequently encountered in patients with underlying conditions such as malignancies, neutropenia, or HIV/AIDS. However, blood cultures are frequently (50 percent) negative in patients with disseminated *Candida* infection (or *Candida* species may not be detected in blood cultures from patients that are also bacteremic) (Hockey et al. 1982). Therefore repeated cultures should be obtained if clinical suspicion of disseminated *Candida* infection is present. In patients with blood cultures positive for *Candida* a possible source of infection should be established, and intravascular catheters should be removed and reinserted at a different site (Rex et al. 1994; Rex 1996). Of note, candiduria may occur secondary to BSI and blood cultures should be obtained if candidemia cannot be ruled out clinically. Crude mortality in patients with nosocomial BSI due to *Candida* species is about 48 percent (Diekema et al. 2003; Wisplinghoff et al. 2004).

Although other fungi, particularly *Aspergillus* species, may cause disseminated infections, blood cultures often remain negative.

ANAEROBIC BACTERIA

Anaerobic bacteria account for about 4 percent of community-acquired and 2 percent of nosocomial BSI (Diekema et al. 2003). Gram-negative anaerobic rods are the most commonly encountered anaerobes in clinical specimens. *Bacteroides fragilis* is the predominant cause of anaerobic BSI (Felner and Dowell 1971; Wilson et al. 1972; Weinstein et al. 1983b; Finegold et al. 1985; Brook 1989; Lombardi and Engleberg 1992). Other gram-negative anaerobes commonly isolated from the blood include *B. thetaiotaomicron* and *Fusobacterium* species. BSI commonly originates from intraabdominal infections, infections of the female genial tract, soft tissue infections, the oropharynx, and the lower respiratory tract (Galpin et al. 1976; Finegold et al. 1985; Brook 1989). Anaerobic gram-negative bacteria isolated from blood cultures usually represent true pathogens (Lombardi and Engleberg 1992), and if isolated from the blood without a clinically apparent source, intraabdominal infection should be considered. Crude mortality rates as high as 60 percent have been reported (Chow et al. 1974) in BSI caused by *Bacteroides* spp. The attributable mortality in *B. fragilis* BSI has been reported as 19 percent (Redondo et al. 1995).

Clostridium species accounted for up to 4.5 percent of BSI in neutropenic patients (Mathur et al. 2002). Other studies reported that about 1 percent of all clinically significant blood culture isolates were identified as *Clostridium* species, most commonly *C. perfringens*, but less frequently also *C. septicum*, *C. difficile*, *C. novii*, and *C. tertium* (Brook 1989; Lark et al. 2001). Predisposing conditions include chronic alcoholism, abdominal surgery, bowel necrosis, septic abortions, malignancies, and decubital ulcers (Brook 1989; Gorbach et al. 1998). *C. perfringens* is isolated from a variety of infections, including BSI in various clinical settings and fulminant septic shock associated with post-abortion infections (Gorbach et al. 1998). In patients with clostridial myonecrosis, most commonly caused by *C. perfringens*, blood cultures are positive in 15 percent of patients (Summanen et al. 2002). However, *C. perfringens* BSI is not always associated with a serious underlying condition (Gorbach et al. 1998).

C. septicum is rarely isolated from anaerobic blood cultures and BSI is usually seen in patients with underlying malignancies, especially leukemia and lymphoma, or carcinoma of the large bowel. Underlying malignancies are present in 70–85 percent of patients with *C. septicum* BSI (Bodey et al. 1991; Kirchner 1991). Other associations include neutropenia and enterocolitis (King et al. 1984; Kudsk 1992). However *C. septicum* has also been isolated from BSI in patients with diabetes mellitus, severe arthritis or gas gangrene (Koransky et al. 1979).

BSI due to anaerobic gram-positive cocci, e.g. *Peptostreptococcus* species, is usually associated with obstetric or gynecological infections (Moll et al. 1996). The clinical significance of *Peptostreptococcus* species recovered from blood cultures is not clear and their isolation should be interpreted with caution.

MICROORGANISMS WITH SPECIAL REQUIREMENTS

Brucellosis

Isolation of *Brucella* species from blood, bone marrow, or tissue cultures in the only irrefutable proof of brucellosis (Young 1995; Solera et al. 1999). Organisms were historically cultured in biphasic bottles (Castaneda) containing a liquid and a solid agar phase. Today, commercial biphasic bottles, lysis centrifugation tubes, and CMBCSs, such as Bact/ALERT and BACTEC9000, are used to isolate *Brucella* species from the blood (Arnow et al. 1984; Solomon and Jackson 1992; Bannatyne et al. 1997; Ozturk et al. 2002). While lysis centrifugation is superior to the Castenada bottles, modern CMBCSs, such as the BACTEC9000, achieve detection times that are similar to those of the lysis centrifugation method (Yagupsky et al. 1997). Details on the performance of automated blood culture systems can be found in a recent review (Yagupsky 1999). Biosafety levels 2 and 3 are recommended for handling of specimens potentially containing *Brucella* species and processing of cultures of *Brucella* species, respectively. In addition to blood cultures, serological testing is mandatory.

Leptospirosis

Since leptospiremia only occurs during the acute phase of the illness (usually 4–7 days), cultures drawn beyond day 10 are likely to be of low yield. Dark-field or phase-contrast microscopy may be used to directly examine the blood. Of note, the detection level is 10^4 organisms/ml (Turner 1970). For culture, media with added rabbit serum or albumin and fatty acids are recommended with the addition of SPS. Tubes are incubated for 4–6 weeks in air at 28–29°C and examined weekly by removing a drop of culture from 1–3 cm below the surface of the medium (Dunne et al. 1997). In addition to blood cultures, serological testing is mandatory.

Bartonellosis

Bartonella henselae, the most common cause of cat scratch disease and *B. quintana*, the etiologic agent of trench fever, have both been associated with bacillary angiomatosis and bacteremia. Both species, as well as *B. elisabethae*, have been isolated from the blood, using conventional, lysis centrifugation or CMBC systems (Dunne et al. 1997). Nutrient-rich media, such as chocolate agar, should be used for subcultures, and prolonged incubation for at least 14 days is required (Anderson and Neuman 1997; Maurin and Raoult 1996).

Mycobacteria

While *M. tuberculosis* is rarely isolated from the bloodstream, *Mycobacterium avium* complex (MAC) is responsible for the majority of disseminated mycobacterial infections and can always be regarded as significant when isolated from the blood (Havlik et al. 1992). Rapidly growing mycobacteria can be cultured from the blood using all commercially available CMBCSs (Waite and Woods 1998; Archibald et al. 2000; Pintado et al. 2001). Survival times of MAC are longer if lysis centrifugation (ISOLATOR) tubes are used (Havlik et al. 1993). Today a variety of systems can be used to process mycobacterial blood cultures, including the ISOLATOR system, the radiometric BACTEC 460TB (BACTEC 13A; detection of $^{14}CO_2$), and the nonradiometric BACTEC 9000MB (BACTEC Myco/F lytic), ESP Culture System II (detection of pressure changes; ESP Myco, Trek Diagnostic Systems) or MB/BacT ALERT 3D (colorimetric CO_2 detection; bioMérieux). All systems use modified Middlebrook 7H9 broth or a similar broth supplemented with a variety of growth factors and antimicrobial agents (Pfyffer et al. 2003). The diagnostic yield of the CMBCSs is similar to that of the BACTEC 460TB and superior to conventional solid media (Pfyffer et al. 1997; Woods et al. 1997; Hanna et al. 1999; Whyte et al. 2000; Piersimoni et al. 2001). The average time to positivity is 5 to 14 days for *M. tuberculosis* and below 7 days for other mycobacteria, when using the BACTEC 460TB and similar detection times for the CMBCSs have been reported (Pfyffer et al. 2003). It is not recommended to transport blood before inoculation of blood culture media; however, if necessary SPS, heparin, EDTA or citrate may be used as anticoagulants (Pfyffer et al. 2003) depending on the culture medium used.

MANAGEMENT OF BLOODSTREAM INFECTION

Progression from bacteremia to sepsis, septic shock, and death can be rapid depending on underlying medical conditions of the host, virulence of the pathogen, and treatment parameters. In a recent study, mortality was double when inappropriate empirical antibiotics were administered to ICU patients with BSI (Ibrahim et al. 2000). Therefore, successful management must include early and appropriate antimicrobial therapy in addition to supportive care and the elimination of a removable focus, if present.

Resistance rates to antimicrobial agents have been rising for the last two decades in all predominant organisms, including *S. aureus* (Edmond et al. 1999; Smith et al. 1999; Trick et al. 2002), CoNS (Diekema et al. 2001), enterococci (Doern et al. 1998), and gram-negative pathogens (Diekema et al. 1999, 2002; Heinemann et al. 2000). In the face of emerging multiresistant organisms, antimicrobial prophylaxis and treatment has become increasingly difficult, and timely and accurate epidemiological information is needed for guiding appropriate empirical therapy. Analyses of *Candida* BSIs have shown trends to selection of non-*albicans* species, some of which are difficult to treat with first generation azoles (Trick et al. 2002). In this context, surveillance programs have become important in defining the species distribution and resistance patterns of pathogens causing BSI, thus providing the basis for appropriate empirical therapy.

INFECTIVE ENDOCARDITIS

INTRODUCTION

Infective endocarditis is a microbial infection of the endocardium, generally of a heart valve or valves, but sometimes of the cordae tendineae or at the site of a septal defect or other congenital abnormalities. With the advent of intracardiac valvular prostheses it was soon realized that these, too, or the tissues into which they are sewn, can also become infected. The term *infective endocarditis* covers the various clinical subcategories of the disease and has replaced the old term *bacterial endocarditis* since it became clear that chlamydiae, rickettsiae, fungi, and probably viruses can also be responsible for the disease. However, endocarditis

caused by these latter agents is not within the focus of this chapter.

Historically, infective endocarditis has been classified as *acute*, *subacute*, and *chronic* endocarditis; this classification was related to the usual course of the untreated disease. The *acute* form is a fulminating infection, characterized by high fever, severe malaise, leukocytosis, and rapid destruction of heart valves and is usually caused by a virulent organism, such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *S. pyogenes*, or *Neisseria gonorrhoeae*. Without treatment, the disease was uniformly fatal resulting in the death of the patient in less than 6 weeks, but sometimes in days. *Subacute* endocarditis referred to infection with unspecific clinical findings and an indolent course with death from the disease occurring after 6 weeks to 3 months, and in the *chronic* form after 3 months and up to 2 years. The acute presentation of the disease usually affected patients without a previous cardiac abnormality, whereas the slowly progressing form of the disease was usually caused by relatively avirulent organisms such as the 'viridans' streptococci and occurred in patients with damaged heart valves.

Although this concept is still very useful mainly for educational purposes, it is less helpful nowadays for the individual patient. Currently, the diagnosis of infective endocarditis based on modern imaging techniques is reached earlier in the course of the disease. In addition, there is considerable overlap in clinical manifestation that is influenced by host factors, virulence determinants, and antimicrobial susceptibility of the offending pathogen, and the timely institution of appropriate antimicrobial therapy, as well as surgical intervention. A classification based on the nature of the causative pathogen may be more appropriate particularly with regard to the different treatment regimens recommended for specific pathogens and clinical prognosis. Mortality associated with infective endocarditis has considerably decreased in the past two decades. With modern diagnostic imaging techniques, the use of standardized antimicrobial therapy, and timely surgical valve replacement if necessary, cure rates approach 90–95 percent for streptococcal endocarditis, whereas infective endocarditis caused by enterococci and in particular *S. aureus* still carries a much higher mortality (Fowler et al. 1999; Cabell et al. 2002). Overall mortality of patients with infective endocarditis, however, has decreased to less than 20 percent in recent years (Cabell et al. 2002; Hoen et al. 2002; Wallace et al. 2002).

EPIDEMIOLOGY

Infective endocarditis is an uncommon disease. In a review of 10 large American series, a frequency of about one case per 1 000 hospital admissions with a range of 0.16–5.4 cases per 1 000 admissions was reported (Bayer and Scheld 2000). Several factors have led to dramatic changes in the epidemiologic features and clinical manifestations of infective endocarditis over the past few decades (Finland and Barnes 1970; Watanakunakorn and Burkert 1993). Among these are the increased life expectancy, a shift in the at-risk population with their predisposing valvular lesions illustrated by a decline of rheumatic carditis and an increase in degenerative valvular disease, an increase in nosocomial cases of infective endocarditis, refined diagnostic imaging techniques, and major advances in cardiothoracic valvular surgery. Most cases of infective endocarditis are acquired in the community, but there are now an increasing number of cases of hospital-acquired (nosocomial) endocarditis and this can affect both native and prosthetic valves (Lamas and Eykyn 1998; Gouello et al. 2000). The incidence of infective endocarditis is difficult to determine due to different patient populations surveyed and since the diagnostic criteria may vary in different series. In the United States and Western Europe, the incidence of infective endocarditis has been estimated to range between two and six cases per 100 000 person-years (van der Meer et al. 1992; Berlin et al. 1995; Hogevik et al. 1995; Hoen et al. 2002) with incidences differing between community-acquired (4.5 cases/100 000 patients-years) versus nosocomial (0.94 cases) endocarditis, as well as native-valve versus prosthetic-valve (0.94 cases) endocarditis (Berlin et al. 1995). The increased longevity has resulted in an increased median age of patients with infective endocarditis, a growing number of patients with cardiovascular disease and prosthetic heart valves, and an increased cumulative exposure to nosocomial bacteremia. Among the population with infective endocarditis associated with intravenous drug abuse, in contrast, there is a trend towards younger patients. In the United States, the incidence of infective endocarditis in this group of patients is estimated at 150–2 000 per 100 000 person-years (Frontera and Gradon 2000); it is much lower in most European countries.

There is a well recognized increased incidence of infective endocarditis with age, and over all the infection is more common in males than females (Hoen et al. 2002). Fifty years ago native valve infective endocarditis was mainly a disease of young people: in Cates and Christie's study (1951) of 442 cases of 'subacute bacterial endocarditis' seen between 1945 and 1948, 62 percent of patients were aged between 15 and 35 years. Since then native valve infective endocarditis has become a disease of the middle-aged and elderly (Gagliardi et al. 1998; Dhawan 2003; Gregoratos 2003).

In earlier series, 60–80 percent of patients with native-valve endocarditis had an identifiable predisposing cardiac lesion (Weinstein and Schlesinger 1974; Watanakunakorn 1977). In a recent population-based survey from France, however, 47 percent among 390 patients with infective endocarditis had no underlying valvular disease (Hoen et al. 2002). Almost any type of structural

heart disease that leads to turbulence of blood flow resulting in endocardial damage may predispose to infective endocarditis, including rheumatic heart disease, congenital heart disease, and arteriosclerotic cardiovascular disease. The proportion of cases of infective endocarditis related to rheumatic heart disease, the primary underlying condition in the past has now declined to less than 25 percent (Kaye 1985), however rheumatic heart disease is still the most common underlying cardiac condition in developing countries (Jalal et al. 1998). Congenital heart disease predisposing to infective endocarditis includes bicuspid aortic valve (Lamas and Eykyn 2000), ventricular septal defect, and tetralogy of Fallot. These conditions were seen previously in 6–24 percent of cases, but in the most recent series reported by Hoen et al. (2002) the frequency of underlying congenital heart disease was only 1 percent. The majority of mainly elderly patients with infective endocarditis and without a history of underlying valvular disease have arteriosclerotic cardiovascular disease with calcified nodular endocardial lesions or an intraventricular thrombus following myocardial infarction. Other conditions associated with infective endocarditis include idiopathic hypertophic subaortic stenosis (IHSS) (Morgan-Hughes and Motwani 2002) and mitral-valve prolapse (Baddour and Bisno 1986), in particular with the presence of mitral valve regurgitation. Hemodialysis shunts (Doulton et al. 2003), intracardiac pacemaker wires (Arber et al. 1994), and central venous catheters (Miele et al. 2001) may also predispose to endocarditis.

Nosocomial infective endocarditis is a rare complication of nosocomial bacteremia. Whilst many aspects of nosocomial infective endocarditis are similar to community-acquired infective endocarditis, both entities differ in their predisposing factors, microbial etiology and prognosis. The increasing use of intravascular access devices for hemodynamic monitoring, administration of fluids, and in particular those used for long-term hyperalimentation and dialysis, has brought a parallel increase in associated nosocomial bacteremia and has contributed largely to the increasing number of hospital-acquired cases of infective endocarditis (Gilleece and Fenelon 2000; Gouello et al. 2000). Other predisposing conditions include advanced age, surgical wounds, genitourinary instrumentation, major abdominal surgery, the implantation of prosthetic valves and cardiac devices, and major burn injury (Cartotto et al. 1998; Fernandez-Guerrero et al. 2002; Giamarellou et al. 2002). Nosocomial endocarditis can affect both previously normal and damaged heart valves, as well as prosthetic valves. *S. aureus* in native valve endocarditis and *S. epidermidis* in the presence of foreign bodies are the main implicated pathogens. Fungal endocarditis can also result from infected intravascular catheters with *Candida* spp. as the most usual pathogens. In their review of 21 cases of endocarditis associated with central venous catheterization, Tsao and Katz (1984) found that two-thirds of cases had right-sided infection, suggesting a parallel with the animal model in which catheter-induced traumatic sterile vegetations become infected after bacteremia. In fact, although catheter-related bacteremia may result in right-sided endocarditis, the infection is not invariably right-sided. In the series reported by Gouello et al. (2000), the overall mortality in patients with nosocomial endocarditis was 68 percent ($n = 15$) and mortality was directly associated with endocarditis in 36 percent of cases ($n = 8$).

Intravenous drug users (IVDU) represent a specific risk group for the acquisition of right-sided but also left-sided infective endocarditis usually without predisposing cardiac disease (Brown and Levine 2002; Moss and Munt 2003). Endocarditis was one of the earliest recognized medical complications of intravenous drug abuse and it is the most common cause of bacteremia in IVDUs. Overall, the predominant pathogen is *S. aureus* (including MRSA), but as with endocarditis not associated with IVDU, a wide spectrum of organisms has been reported. These include pyogenic streptococci, pseudomonads, other gram-negative bacilli and fungi, as well as polymicrobial infections. Most cases involve a previously normal tricuspid valve and result from repeated intravenous injection of foreign material and organisms. Left-sided endocarditis is uncommon in IVDUs unless they have previous heart disease, but appears to be increasing (Seghatol and Grinberg 2002). Tricuspid endocarditis presents with the signs of systemic infection and respiratory symptoms from septic pulmonary emboli and not with the 'classical signs' of endocarditis. Such symptoms (and the chest X-ray findings) may be misdiagnosed as pneumonia by clinicians unfamiliar with right-sided endocarditis. The disease is more frequent in HIV-positive or than in HIV-negative IVDUs, but the presentation and clinical manifestations are similar (Wilson et al. 2002). The causative organisms are usually acquired from the patient's own flora although the drug 'works' have been implicated in cases of *P. aeruginosa* infection. Most IVDUs with tricuspid endocarditis have a good prognosis, but the mortality rate is markedly increased in those with very large vegetations and left-sided involvement.

Prosthetic-valve endocarditis accounts for 10–25 percent of cases of infective endocarditis in developed countries (Hogevik et al. 1995; Fefer et al. 2002; Hoen et al. 2002). It has been estimated that between 3 and 6 percent of patients develop prosthetic-valve endocarditis within the first 5 years following surgery (Calderwood et al. 1985; Agnihotri et al. 1995).

PATHOGENESIS

The development of infective endocarditis usually follows a multifactorial course. Alterations of the valve surface and less frequently the epithelial lining of the heart chamber (mural endocarditis) represent the first

step in this series of events. These lesions, induced by high velocity turbulent blood flow across the valve results from a variety of local or systemic stresses, such as a small ventricular defect or a valvular stenosis. The location of valvular jet lesions is determined by the direction of the accelerated bloodstream, i.e. they are usually located on the low-pressure side of the cardiac valves, such as the atrial surface of an insufficient mitral or tricuspid valve and the ventricular surface of an incompetent aortic valve. Any endothelial lesion results in exposure of the underlying extracellular matrix (ECM) proteins, the production of tissue factor, the deposition of platelets and fibrin, and the formation of so-called *sterile vegetation*. These deposits are characteristic of nonbacterial thrombotic endocarditis (NBTE) (Blanchard et al. 1992), a condition also seen to be associated with chronic wasting diseases, particularly malignancy (marantic endocarditis), connective tissue diseases, and intracardiac catheters.

Infective endocarditis occurs when microorganisms are deposited on to the sterile vegetation during an episode of transient bacteremia. Transient bacteremia results from mechanical manipulation of mucosal surfaces colonized with bacteria, such as with dental extractions or other dental procedures (Coulter et al. 1990; Bayliss et al. 1983), endoscopy and/or biopsy of the gastrointestinal (Rigilano et al. 1984; Schlaeffer et al. 1996) or the urogenital tract (Zimhony et al. 1996), and surgical procedures leading to injury of these organs. Such a history, however, is only obtained in a minority of patients with infective endocarditis. Studies have also demonstrated spontaneous transient bacteremia in patients with poor dentition even in the absence of dental procedures whilst chewing or brushing their teeth (Bhanji et al. 2002). These procedures may also induce bacteremia in people with good oral hygiene. Bacteremia is low grade (<10 organisms per ml) and transient, i.e. the bloodstream is usually cleared from the invading bacteria within 15–30 min.

Infective endocarditis can also occur in the absence of a known or identifiable pre-existing valve lesion. This is particularly true for virulent, invasive pathogens such as *S. aureus*. This organism may bind directly to endothelial cells, a property that explains the ability of *S. aureus* to initiate endocarditis on 'normal' cardiac valves, in particular those of the elderly with some degree of degenerative valve sclerosis and IVDUs in whom valvular damage may be induced by repeated injection of impure materials (Clifford et al. 1994).

The adherence of a microorganism to platelets and fibrin is the next critical step in the development of endocarditis. Numerous studies have demonstrated a correlation between the ability of bacteria to adhere in vitro to platelet-fibrin matrices mimicking NTBE and their propensity to induce infective endocarditis in humans and in animal models (Scheld et al. 1978; Ramirez-Ronda 1978). Certain organisms such as viridans group streptococci, enterococci, and staphylococci – the predominant pathogens involved in infective endocarditis – adhere more avidly to normal canine endocardial surfaces in vitro than enteric bacilli, such as *Escherichia coli* and *Klebsiella pneumoniae* (Gould et al. 1975). *S. aureus* and *S. pneumoniae* appear to have a particular propensity to adhere to fibrin-platelet deposits and thus may produce infective endocarditis with a lower inoculum. Adherence is mediated by bacterial surface molecules interacting with host ECM molecules. These are termed microbial surface components recognizing adhesive matrix molecules (MSCRAMM). Streptococci and staphylococci carry multiple MSCRAMMs that mediate binding to NTBE and directly to endothelial cells.

The adherence of oral streptococci to NBTE lesions may be promoted by their ability to produce dextran or glucan, a complex extracellular surface polysaccharide, which in the case of *S. mutans* is also involved in the pathogenesis of dental caries (Gibbons and Nygaard 1968). Glucan production may thus be one of several virulence factors required for infection. Since not all species of streptococci that cause infective endocarditis are glucan producers (including most strains of *S. oralis*, one of the most common of the oral streptococci to cause infective endocarditis), other factors must also be involved in the pathogenesis of infective endocarditis caused by viridans streptococci and enterococci. One example is FimA, a surface adhesin located at the tips of the fimbriae that has been shown to mediate the attachment of *S. parasanguis* to fibrin-platelet matrices (Burnette-Curley et al. 1995). Inactivation of FimA greatly decreased the organisms' ability to induce endocarditis in rats. FimA-like proteins were found in a number of streptococcal species. Another factor involved in the pathogenesis of streptococcal endocarditis is the ability to bind to fibronectin which probably acts as the host receptor within the NBTE (Lowrance et al. 1990).

In contrast to less virulent organisms, such as the streptococci that usually implant only on cardiac sites with pre-existing endothelial lesions (Sullam et al. 1987; Kitada et al. 1997a; McCormick et al. 2000), *S. aureus* can either colonize damaged endothelium or invade physically intact endothelial cells (Yao et al. 1995). The major adhesins involved in the binding of *S. aureus* to NBTE lesions are its fibrinogen-binding proteins such as clumping factor and coagulase (Devitt et al. 1994; Moreillon et al. 1995). The expression of these factors is regulated by the global regulators: accessory gene regulator (*agr*), staphylococcal accessory regulator (*sar*) and probably other determinants (Cheung and Projan 1994). *S. aureus* may also bind directly to and invade endothelial cells, a property mediated by fibronectin-binding proteins FnBPA and FnBPA (Vercellotti et al. 1984; Kuypers and Proctor 1989; Flock et al. 1996; Menzies 2003).

Local bacterial survival and persistence is the next step involved in the development of infective endocarditis. Following bacterial adherence to and colonization of NBTE lesions, the organisms are rapidly covered with more fibrin and platelets which form a protective sheath that shelters the bacteria from host phagocytes and soluble host defenses, as well as from antimicrobials and permits further bacterial proliferation and vegetation growth. Local production of tissue factor (TF) by host monocytes and endothelial cells and aggregation of platelets are mainly involved in this process (Sullam et al. 1996). Additional factors produced by staphylococci, such as hemolysins, may disrupt the endothelial envelope of adjacent cells and allow further tissue invasion and enlargement of the infectious process (Moreillon et al. 2002). These conditions allow for unimpaired bacterial multiplication leading to extremely high colony counts of 10^9 to 10^{11} bacteria per gram of tissue. Bacteria residing deeply within the vegetation can adopt a reduced metabolic state that enables them to resist the attack of beta-lactam antibiotics which exert their action mainly on proliferating bacteria. These fresh vegetations are thus composed of bacterial masses, fibrin, platelet aggregates, rarely red blood cells, and inflammatory cells. The morphology of the vegetations can range from small, flat, granular lesions a few millimeters in size, to large, soft, pedunculated, friable masses several centimeters in size. They may or may not progress to further valvular, perivalvular, or extracardiac complications, resulting from embolic phenomena such as embolization into the coronary arteries or the systemic arterial tree leading to ischemia, infarcts, bleeding, and abscess formation. The same factors involved in both vegetation growth and tissue destruction are likely to be responsible for bacterial dissemination to remote sites where colonization of target tissue probably involves the same infection cycle starting with tissue adherence. During the course of healing, infiltration by polymorphonuclear leukocytes and fibroblasts results in fibrosis and sometimes calcification of the lesion which finally will become covered by endothelium.

Infective endocarditis, like other infectious diseases, is associated with circulating immune complexes that are found in high titers in virtually all patients (Bayer et al. 1976; Bayer and Theofilopoulos 1990). Some of the peripheral manifestations of infective endocarditis, such as Osler nodes and Roth spots as well as glomerulonephritis, may result from deposition of circulating immune complexes.

MICROBIOLOGY

A multitude of microorganisms has been implicated in infective endocarditis, and heart valves, in particular prosthetic valves, can become infected with just about any microbe or fungus. The majority of cases are caused by a fairly limited number of pathogens, i.e. streptococci and staphylococci. The most common etiologic agents are listed in Table 5.

Table 5 *Distribution of etiologic agents in patients with infective endocarditis*

	% of cases	
Microorganism	**Mean**	**Range**
Streptococci	50	35–53
Viridans streptococci	33	17–48
Other streptococci	17	5–33
Enterococci	8	6–10
Staphylococci	30	29–38
Staphylococcus aureus	23	22–31
Coagulase-negative staphylococci	7	6-8
Gram-negative aerobic bacilli	3	1–3
Fungi	1	0–1
Other bacteria	2	1–4
Polymicrobial infections	3	3–4
Culture-negative	8	6–12

Data are compiled from three population-based studies comprising 927 patients with infective endocarditis (van der Meer et al. 1991; Hogevik et al. 1995; Hoen et al. 2002).

Streptococci and *enterococci*

Nearly two-thirds of cases of community-acquired native valve infective endocarditis are caused by streptococci and enterococci: 214 of 326 (65.6 percent) in a Dutch series and 226 of 390 (58 percent) in a recent population-based survey in France (van der Meer et al. 1991; Hoen et al. 2002). However, streptococcal and enterococcal infective endocarditis cannot be considered as a homogeneous entity since both the pathogenesis of the infection and the disease itself differ according to the species responsible.

The largest group are the oral streptococci which are usually referred to as the 'viridans' group streptococci because most produce α-hemolysis (greening) when cultured on blood agar. While clearly predominating in the past, oral streptococci were responsible for less than 20 percent of the cases in more recent series and declined significantly from 7.8 cases per million person-years in 1991 to 5.1 cases per million person-years in 1999 (Hoen et al. 2002). For many years the oral streptococci were known as '*Streptococcus viridans*', but this is inaccurate because this term suggests a species designation. In fact, the oral streptococci constitute a heterogeneous group of different species within the genus *Streptococcus* which are usually nontypable by the Lancefield system. The taxonomy of the streptococci is confusing and has undergone major taxonomic changes. These taxonomic changes are well reviewed by Facklam (2002), but it seems that further reclassification of some species is inevitable. The oral streptococci include *S. gordonii*, *S. mitis*, *S. mutans*, *S. oralis*, *S. salivarius*,

S. sanguinis (previously *S. sanguis*), and the 'nutritionally variant streptococci' (now classified as *Abiotrophia* and *Granulicatella* spp.), as well as some others. *S. morbillorum* is now classified as *Gemella morbillorum*. In Parker and Ball's study (1976) of streptococci associated with systemic disease, the oral streptococci so defined accounted for about two-thirds of the 317 streptococci isolated from the blood in patients with infective endocarditis. Among the 225 streptococci reported in the French series (Hoen et al. 2002), 68 (30 percent) were identified as oral streptococci, while 98 (44 percent) were group D streptococci (including *S. bovis*, *S. gallolyticus*, and *S. infantarius*) and 22 (10 percent) belonged to the pyogenic streptococci. Many of the oral streptococci seldom cause infection other than infective endocarditis. Thus, the presence of these organisms in blood cultures, particularly in more than one set, should raise the suspicion of infective endocarditis even in the absence of any other clinical sign and symptom and prompt appropriate diagnostics such as transesophageal echocardiography (TEE) (see below). In fact, in such cases the microbiologist may often be able to provide the clinician with the necessary clue as to the etiology of the patient's illness and thus initiate an appropriate diagnostic approach and antimicrobial therapy.

The different species of oral streptococci differ in their habitat and in their propensity to cause infective endocarditis. A recent report of the identification of 47 strains of oral streptococci from cases of infective endocarditis found that 31.9 percent were *S. sanguis*, 29.8 percent *S. oralis*, and 12.7 percent *S. gordonii*. Other species were much less common (Douglas et al. 1993).

Cates and Christie (1951) in their study of 'subacute bacterial endocarditis' 40 years ago found that only 12.3 percent of their 187 cases of 'viridans' streptococcal endocarditis had had a tooth extraction less than 3 months before the onset of symptoms, whereas 34.8 percent had dental sepsis or caries. More than 30 years later, Bayliss et al. (1983) reported a similar incidence of 13.7 percent of cases occurring within 3 months of a dental procedure. Even if there is no overt dental focus it can still be assumed that the oral streptococci have originated in the mouth. Transient bacteremia with oral streptococci may also follow procedures such as tonsillectomy or adenoidectomy and (rarely) bronchoscopy or gastroscopy, but there is no evidence that these procedures result in infective endocarditis.

There are currently three recognized species that are traditionally referred to as the *S. milleri* group, *S. anginosus*, *S. constellatus*, and *S. intermedius*. Unlike the viridans group streptococci, organisms of the *S. milleri* group seldom cause native valve endocarditis. These organisms, in particular *S. anginosus*, are commonly isolated from septic lesions at a variety of sites, including abscesses of internal organs, such as the liver and brain, as well as from cholangitis, peritonitis, and empyema, either in pure culture or more commonly in polymicrobial infections with anaerobes (Casariego et al. 1996; Bert et al. 1998). However, *S. milleri* group infective endocarditis does not occur in association with such septic conditions; it seems to be an entirely separate entity (Kitada et al. 1997b; Marinella 1997; Lefort et al. 2002). A Dutch study (van der Meer et al. 1991) is the only published series with data on species distribution within this group. In a total of 326 cases of native valve infective endocarditis they reported 12 cases of *S. intermedius* and three of *S. constellatus* (interestingly no *S. anginosus*), giving an overall incidence for the *S. milleri* group of 4.6 percent. This is similar to the 2–5 percent incidence in the five reports quoted by Douglas et al. (1993), although they included prosthetic infections as well as native. Infective endocarditis caused by *S. anginosus* tends to be a more acute and severe infection associated with intracardiac complications that are more commonly seen with *S. aureus* (Levandowski 1985; Hurle et al. 1996).

Nutritionally variant streptococci (NVS), recently classified as *Granulicatella (Abiotrophia) adiacens* and *A. defectiva*, do not grow on subculture unless specific growth factors are added, therefore isolation and correct identification of these species is often difficult. These organisms accounted for 2 percent of cases of infective endocarditis in the French series (Hoen et al. 2002). The disease usually runs an indolent course and is associated with pre-existing valvular heart disease and illicit drug use (Leonard et al. 2001; Chang et al. 2002). However, complications such as systemic embolization frequently occur and are responsible for the relatively high mortality rate (Christensen et al. 1999).

S. bovis is a normal inhabitant of the gastrointestinal tract and is only seldom found in the mouth. In the past, this organism was often misidentified as *Enterococcus* (previously *Streptococcus*) *faecalis* since the two species share the Lancefield group D antigen and are biochemically quite similar. Other members of the group D streptococci with pathogenic significance include *S. gallolyticus* and *S. infantarius*, previously classified as different *S. bovis* biotypes. With the advent of commercial streptococcal identifiation kits such as the API 20 Strep and Rapid ID 32 Strep (bioMérieux), which are commonly used in many laboratories, correct identification of *S. bovis*, which is important since it involves a different therapeutic approach, has become much easier. *S. bovis* was as common as *S. sanguis* and *S. oralis* (*S. mitior*) as a cause of streptococcal infective endocarditis in Parker and Ball's (1976) series in which it was responsible for 15.8 percent of 317 cases and for nearly a quarter of the cases in patients over 55 years. Comparing the etiologic agents of infective endocarditis between two surveys performed in 1991 and 1999, Hoen et al. (2002) noted an increase of Group D streptococci from 5.3 in 1991 to 6.2 cases per million person-years in 1999. The clinical manifestations of *S. bovis* infective endocarditis are similar to those caused by 'viridans' streptococci (Ballet

et al. 1995; Duval et al. 2001; Pergola et al. 2001). In 1977, Klein et al. reported two patients with *S. bovis* endocarditis and adenocarcinoma of the colon. Since then others have noted an association between *S. bovis* bacteremia and not only colonic cancer but also polyposis and other gastrointestinal disorders (Leport et al. 1987; Waisberg et al. 2002). In their study of 90 cases of *S. bovis* bacteremia during the period 1951–1980, Honberg and Gutschik (1987) identified 15 patients (17 percent) with gastrointestinal cancer and concluded that there was a high frequency of neoplasms in patients with a history of *S. bovis* bacteremia, particularly in those with endocarditis, even several years after the episode of bacteremia. Leport et al. (1987), in a study of 77 cases of group D streptococcal endocarditis, found a significantly higher frequency of colonic polyps and neoplasms in patients with *S. bovis* endocarditis than in those with enterococcal endocarditis and they and others emphasized the need for colonoscopy in any patient with *S. bovis* bacteremia (Klein et al. 1977; Beeching et al. 1985).

In the pre-antibiotic era, *S. pneumoniae* accounted for about 10 percent of cases of infective endocarditis (Powderly et al. 1986), but it is now rarely seen. In a nationwide survey conducted in France between 1991 and 1998, 30 cases of native valve pneumococcal endocarditis were observed; the majority of patients (66.7 percent) had no predisposing cardiac condition (Lefort et al. 2000). The primary focus of infection in one-third of patients was pneumonia. Pneumococcal endocarditis causes an acute fulminating infection, generally of a previously normal valve, most often the aortic valve, and complications such as large arterial emboli, perivalvular abscess formation, and rapid valve destruction are frequent (Aronin et al. 1998; Lindberg et al. 1998; Lefort et al. 2000). The infection tends to occur in alcoholics and these patients usually have concomitant pneumonia and meningitis, a triad called Austrian's syndrome (Munoz et al. 1999). The overall mortality remains high at approximately 25–50 percent, valve replacement is frequently necessary, and penicillin resistance is a cause of concern (Lefort et al. 2000; Martinez et al. 2002).

Alpha-hemolytic pyogenic streptococci of Lancefield groups A, B, C, and G only occasionally cause endocarditis, usually attacking normal valves. The patterns of infective endocarditis caused by these organisms were recently reviewed by Lefort et al. (2002). The group B streptococci (*S. agalactiae*) are by far the most common and their incidence has recently increased (Gallagher and Watanakunakorn 1986; Scully et al. 1987; Baddour 1998; Hoen et al. 2002; Sambola et al. 2002). In the Spanish series (Sambola et al. 2002) *S. agalactiae* accounted for 2.6 percent of native valve endocarditis and a similar figure of 2.8 percent was found in a Dutch series (van der Meer et al. 1991). Although group B streptococci have a well recognized though unexplained predilection for diabetics, most cases of infective endocarditis do not occur in diabetic patients. Other risk factors for group B streptococcal bacteremia and infective endocarditis include carcinoma, alcoholism, hepatic failure, and intravenous drug use (Farley 2001). They are aggressive pathogens and, as in staphylococcal endocarditis, other sites of infection are often found; these include septic arthritis, vertebral osteomyelitis, meningitis, and endophthalmitis. The overall mortality has decreased in the Spanish series from 61 percent in 1975–1992 to 8 percent in 1993–1998 probably due to earlier cardiac surgery. Similar clinical manifestations are seen with group G streptococcal endocarditis with left-sided involvement, frequent complications, and considerable mortality (Venezio et al. 1986; Smyth et al. 1988; Liu et al. 1995). Group A streptococci (*S. pyogenes*) remain a very rare cause of infective endocarditis (Burkert and Watanakunakorn 1991; Liu et al. 1992; Mohan et al. 2000).

In a nationwide prospective survey in Sweden (Olaison and Schadewitz 2002), enterococci accounted for 11 percent of cases of infective endocarditis; in the Dutch series they accounted for 7.4 percent of 326 cases (van der Meer et al. 1991), and a nearly identical figure of 8 percent was reported in the most recent survey from France (Hoen et al. 2002). Enterococcal endocarditis is usually considered a community-acquired disease; however the incidence of nosocomial acquisition appears to be increasing (Fernandez-Guerrero et al. 2002). Enterococci are normal inhabitants of the gastrointestinal tract and occasionally the anterior urethra and they may cause urinary tract infection, particularly after instrumentation. Enterococcal bacteremia has been reported after colonoscopy, proctoscopy, sigmoidoscopy and barium enema, prostate biopsy, and abdominal tract surgery (Caballero-Granado et al. 2001). Most enterococcal bacteremias are nosocomial in origin, associated with invasive procedures, and often polymicrobial. Factors suggesting infective endocarditis in patients with enterococcal bacteremia include community acquisition, underlying valvular heart disease, the absence of another likely portal of entry, and monomicrobial bacteremia. Most cases of infective endocarditis are caused by *Enterococcus faecalis*, but there are occasional cases of other species such as *E. faecium*, *E. avium*, *E. durans*, and *E. gallinarum* (Dargere et al. 2002). Enterococcal endocarditis is most commonly seen in elderly men. Enterococcal bacteruria may be a helpful diagnostic clue. The disease usually runs a subacute course and classic peripheral manifestations are often absent. In cases of enterococcal infective endocarditis, both normal and previously damaged valves, as well as prosthetic valves can be involved (Rice et al. 1991). Enterococcal endocarditis is more difficult to treat than streptococcal endocarditis because enterococci are intrinsically more resistant to antibiotics than streptococci. However, with standard

treatment and the appropriate use of valve replacement, a cure rate of approximately 85 percent can be expected (Megran 1992).

Staphylococci

An ever increasing number of cases of infective endocarditis, both community-acquired and of nosocomial origin, are caused by staphylococci (Cabell et al. 2002). These organisms accounted for nearly 30 percent of infective endocarditis in the large population-based survey in France (Hoen et al. 2002) and their incidence increased from 4.9 cases per million person-years in 1991 to 5.7 cases per million person-years in 1999. Most of these staphylococci are *S. aureus*, but an increasing proportion are now coagulase-negative staphylococci (Hogevik et al. 1995; Cabell et al. 2002; Hoen et al. 2002).

Some 80–90 percent of the staphylococci isolated from cases of community-acquired native valve infective endocarditis are *S. aureus*. This organism can attack 'normal' heart valves (i.e. in patients without detectable cardiac disease) in one-third of the patients or damaged valves in patients with an underlying cardiac condition, producing severe fulminating infection that results in death in approximately 40 percent of patients (Petti and Fowler 2003; Hasbun et al. 2003). The infection arises from a bacteremia which itself stems from a trivial septic lesion such as wound infection, from an episode of catheter-related bacteremia occurring during a previous hospitalization, and often with no detectable focus (Mylotte et al. 1987; Eykyn 1988; Fowler et al., 1998; Mylotte and Tayara 2000a). Infective endocarditis caused by *S. aureus* has been traditionally regarded as a largely community-acquired disease. However, a recent study from Duke University revealed that among 59 definite cases of *S. aureus* infective endocarditis nearly half of the cases were hospital-acquired and were frequently caused by methicillin-resistant *S. aureus* (Fowler et al. 1999). The authors underscore the association of intravascular-device related *S. aureus* bacteremia and the development of infective endocarditis and recommend complete diagnostic evaluation including TEE (see below) for underlying infective endocarditis in any case of nosocomial bloodstream infection caused by *S. aureus*.

The disease often runs a rapidly progressive, *acute* course (Thompson 1982; Roder et al. 1999). Heart murmurs are seldom present initially unless there was a previous cardiac abnormality. The physician is thus confronted with a toxic ill patient with *S. aureus* recovered from a blood culture and sometimes without localizing signs. In about a quarter of cases the urine will contain both pus cells and staphylococci, the result of microabscesses in the kidney, and this can lead to further diagnostic confusion. Embolic phenomena involving the brain, spleen, or kidney, as well as the classic peripheral stigmata of infective endocarditis are more common in staphylococcal endocarditis than in endocarditis caused by other microorganisms. Intracardiac complications such as valve ring or myocardial abscess formation, and purulent pericarditis are frequently observed. Valvular destruction leading to congestive heart failure and death may occur within days (Watanakunakorn et al. 1973; Bayer 1982; Sanabria et al. 1990). This, the classical presentation of staphylococcal endocarditis, was accurately described over a century ago by William Osler in his Gulstonian lectures on 'malignant endocarditis' (1885), but it still seems largely unknown to many clinicians. Any patient who is unwell with a *S. aureus* bacteremia but no obvious site of infection should be assumed to have infective endocarditis and treated accordingly. Native valve infective endocarditis with *S. aureus* may occur at any age, but is more common in the middle-aged and elderly where mortality may exceed 50 percent (Julander 1985; Sanabria et al. 1990); it occurs in the previously healthy, as well as in those with underlying diseases such as diabetes mellitus and end-stage renal disease (Marr et al. 1998; Maraj et al. 2002; Doulton et al. 2003).

S. aureus is also the most common cause of infective endocarditis in intravenous drug users (IVDU) and is often associated with HIV infection (Mathew et al. 1995; Miro et al. 2003). However, since right-sided involvement mainly affecting the tricuspid valve predominates in these patients, the disease tends to be less severe than in non-addicts and usually responds to antimicrobial therapy alone with mortality rates below 10 percent.

Although still regarded by many as pathogens involved in prosthetic rather than in native valve endocarditis, coagulase-negative staphylococci also cause native valve infection and this has become more common, or certainly more commonly recognized, since the early 1980s (Caputo et al. 1987; Etienne and Eykyn 1990; Whitener et al. 1993; Miele et al. 2001). In the French series, coagulase-negative staphylococci accounted for 6.4 percent of cases of infective endocarditis (Hoen et al. 2002), and the Dutch series (van der Meer et al. 1992) reported a similar incidence (4.9 percent). In both studies it was not specified whether the infections were community- or hospital-acquired. Coagulase-negative staphylococci are normal inhabitants of the skin and mucous membranes and different species vary in their distribution throughout the body. Thus, it seems likely that native valve coagulase-negative staphylococcal infective endocarditis is an endogenous infection, even in cases of nosocomial acquisition associated with the use of intravascular catheters. In community-acquired cases a predisposing skin lesion is rarely detected and the oropharynx can be considered a likely portal of entry similar to the case with viridans streptococcal endocarditis. Approximately two-thirds of patients have pre-existing cardiac valvular disease

(Baddour et al. 1986). The clinical course is usually indolent (*subacute*) in onset and complications such as embolic disease and congestive heart failure are rare. Separating infective endocarditis from uncomplicated bacteremia due to coagulase-negative staphylococci or even from contamination may be difficult. Continuously positive blood cultures – in nosocomial cases in particular after intravascular catheters have been removed – may be an important clinical clue to the diagnosis.

The infecting species is most often *S. epidermidis* (Etienne and Eykyn 1990). However, in many reports the designation *S. epidermidis* tends to be used for any unspeciated coagulase-negative staphylococcus. With the advent of commercial identification systems, species identification of coagulase-negative staphylococci has become much easier. Thus, many other species have been reported to cause rare cases of native valve infective endocarditis, including *S. capitis*, *S. caprae*, *S. hominis*, *S. lugdunensis*, *S. saprophyticus*, *S. sciuri*, *S. schleiferi*, *S. simulans*, and *S. warneri* (Singh and Raad 1990; Leung et al. 1999; Sandoe et al. 1999; Hoen et al. 2002). Of these, *S. lugdunensis* appears to cause a more fulminate disease than that due to other coagulase-negative staphylococci (Vandenesch et al. 1993; Burgert et al. 1999; Farrag et al. 2001; Seenivasan and Yu 2003). These organisms are frequently misidentified as *S. aureus* owing to their morphological appearance when cultured on blood agar with yellow pigmentation and complete β-hemolysis.

Gram-negative bacilli

A small proportion of cases – 6.1 percent in the Dutch series (van der Meer et al. 1992), and 1.5 percent in the French series (Hoen et al. 2002) – of community-acquired native valve endocarditis are caused by gram-negative bacilli, the vast majority of these are fastidious, nonenteric organisms that tend to grow slowly on primary isolation from blood cultures or that cannot readily be isolated on conventional culture media. They include species that have a predilection for the heart valve and rarely cause infections other than infective endocarditis, as, for example, those known as the HACEK group (*Haemophilus aphrophilus*, *H. paraphrophilus*, *H. parainfluenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*), whose isolation from blood cultures is virtually diagnostic of infective endocarditis (Das et al. 1997; Feder et al. 2003). The disease usually runs a subacute course and occurs in the setting of pre-existing valvular disease. Large friable vegetations are common, as are frequent emboli, and often the need for valve replacement. However, with early diagnosis and institution of appropriate antimicrobial therapy, prognosis is usually favorable. The slow growth of these organisms in blood cultures necessitates incubation of blood cultures from all patients with presumptive infective endocarditis for at least 3 weeks.

Other fastidious gram-negative rods that have been implicated in infective endocarditis include *Acinetobacter* spp. (Gradon et al. 1992), *Brucella* spp. (Jacobs et al. 1990), *Campylobacter fetus* (Farrugia et al. 1994), *Francisella tularensis* (Tancik and Dillaha 2000), *Haemophilus influenzae* (Geraci et al. 1977), and *Streptobacillus moniliformis* (Rupp 1992). Valve replacement is usually necessary for cure of *Brucella* endocarditis (Jacobs et al. 1990; Keles et al. 2001).

Gram-negative enteric bacilli, although frequently isolated from blood cultures, are only rarely a cause of infective endocarditis (Cohen et al. 1980). Drug addicts, patients with prosthetic heart valves, and patients with liver disease are at increased risk for the development of enterobacterial endocarditis. Sustained gram-negative bacillary bacteremia despite adequate antimicrobial therapy should herald possible infective endocarditis. A fulminate clinical course resulting in congestive heart failure is common and the prognosis usually poor (Carruthers 1977; Geraci and Wilson 1982). *Salmonella* spp., in particular *S. cholerasuis*, *S. typhimurium*, and *S. enteritidis* were most frequently encountered in earlier reports (Schneider et al. 1967), with valvular destruction, intracardiac complications, and rapidly progressive congestive heart failure, commonly observed. *Salmonella* endocarditis has been found in both native and prosthetic valve endocarditis (Goerre et al. 1998) and is also associated with HIV infection (Fernandez Guerrero et al. 1996). High overall mortality was also seen with infective endocarditis caused by *Serratia marcescens* (Mills and Drew 1976), as well as *Pseudomonas aeruguinosa* (Wieland et al. 1986; Komshian et al. 1990). Both organisms have been mainly recovered from patients with infective endocarditis who have abused intravenous drugs. *Pseudomonas aeruginosa* frequently affects normal valves, and complications include embolic phenomena, splenic abscesses, valve ring abscesses, and congestive heart failure. Due to the poor prognosis with medical therapy alone, early surgical intervention has been advocated if left-sided cardiac involvement is present (Wieland et al. 1986; Komshian et al. 1990).

Other bacteria

The nondiphtheriae corynebacteria are major components of the normal flora of human skin and mucous membranes. As such, they are frequently dismissed as contaminants if isolated from clinical specimens. However, these organisms are also uncommon, but increasingly recognized as agents of endocarditis in patients with underlying structural heart disease or prosthetic valves (Ross et al. 2001; Knox and Holmes 2002). Among the species reported are *Corynebacterium amycolatum*, *C. jekeium*, *C. striatum*, and *C. xerosis*.

However, methods that reliably differentiate related species are not available in most routine diagnostic laboratories. Other rare, gram-positive rods implicated in infective endocarditis include *Erysipelothrix rusiopathiae* (Venditti et al. 1990), *Lactobacillus* spp. (Husni et al. 1997), and *Listeria* spp. (Spyrou et al. 1997).

Anaerobes are found as normal inhabitants in the human mouth with or without dental caries and they represent the predominant flora of the bowel. However, these organisms have rarely been reported to cause endocarditis. According to Felner and Dowell (1970), non-streptococcal anaerobic bacteria accounted for 1.3 percent of cases of infective endocarditis and some other authors have reported a higher incidence, especially in IVDUs and polymicrobial infections. *Bacteroides fragilis* was the predominant pathogen in a review of 67 cases published by Nastro and Finegold (1973). Other anaerobes recovered from patients with infective endocarditis include other *Bacteroides* spp., *Clostridium* spp., *Fusobacterium* spp., and *Propionibacterium acnes* (Lortholary et al. 1995; Mohsen et al. 2001; Brook 2002).

Endocarditis due to rare and fastidious bacteria has recently been reviewed by Berbari et al. (1997) and by Brouqui and Raoult (2001). Some 350 cases of endocarditis caused by *Coxiella burnetii*, the etiologic agent of Q fever, have been described in the medical literature. Endocarditis is a recognized, though rare (and very late) sequel of acute *C. burnetii* infection. Most infections occur in middle-aged men usually (88.5 percent) with pre-existing heart disease (Marrie and Raoult 2002). The reservoir of the organism is sheep and cattle, but the source and mode of transmission of this anthropozoonosis to humans often remains unclear. Occupational exposure was reported in 12.5 percent of endocarditis patients. In contrast to most other cases of infective endocarditis, the diagnosis is usually made serologically although *C. burnetii* can be recovered on culture with special techniques (Houpikian and Raoult 2003). In view of this it is likely that *C. burnetii* endocarditis is underdiagnosed and some cases falsely labeled 'culture-negative' endocarditis.

Other organisms occasionally causing infective endocarditis that cannot be isolated in routine laboratories include *Bartonella* spp. (Spach et al. 1995; Raoult et al. 2003), *Chlamydia* spp. such as *C. psittaci*, the agent of psittacosis, and *C. pneumoniae* (Marrie et al. 1990; Brouqui and Raoult 2001), *Mycoplasma* spp. (Popat et al. 1980; Cohen et al. 1989), and *Tropheryma whipplei*, the agent of Whipple's disease (Fenollar et al. 2001; Richardson et al. 2003).

'CULTURE-NEGATIVE' ENDOCARDITIS

Most reported series of infective endocarditis include a variable number of cases that are designated *culture-negative*, that is they have negative blood cultures while other criteria of infective endocarditis such as echocardiographic demonstration of vegetations or histological evidence at surgery (see Clinical manifestations and complications) are met (Pesanti and Smith 1979; Tunkel and Kaye 1992; Hoen et al. 1995; Kupferwasser and Bayer 2000; Lamas and Eykyn 2003; Werner et al. 2003). The reported incidences varied ranging from 12 to 24 percent. Blood cultures remained negative in 9 percent of the cases recently reported by Hoen et al. (2002). Some earlier studies used poorly defined diagnostic criteria and possibly inadequate culture techniques. There are various explanations for the phenomenon of culture-negative endocarditis.

Previous administration of antibiotics will reduce the incidence of positive blood cultures, particularly in streptococcal infective endocarditis. The diagnosis of infective endocarditis is often initially missed in patients who do not present with classical 'textbook' signs, and these will be treated with antibiotics empirically before this diagnosis is being considered and blood cultures are taken. In the series reported by Werner et al. (2003), 45 percent of patients with culture-negative endocarditis had received prior antimicrobial therapy. The duration of previous antibiotic therapy is also an important factor. After only 2–3 days of antibiotic treatment, blood cultures that were initially negative after prolonged incubation often then become positive, but after longer courses they may remain persistently negative. In such cases, the antibiotics should be stopped and repeated blood cultures performed for a period up to 5 days.

Fastidious slow growing organisms are uncommon causes of infective endocarditis, but may take much longer to grow in blood cultures than the more usual 'viridans' streptococci or staphylococci. Examples include the HACEK group, the nutritionally variant streptococci such as *Granulicatella (Abiotrophia) adiacens* and *A. defectiva*, *Legionella* spp. (Chen et al. 1996) as well as mycobacteria (Cope et al. 1990) and some anaerobes. In such cases infective endocarditis only initially appears *culture-negative*, but cultures eventually become positive if they are held for the recommended 3 weeks and/or are subcultured on to appropriate media, respectively.

Organisms requiring special isolation techniques or serological diagnosis include *Bartonella* spp., *Chlamydia* spp., *C. burnetii*, *Mycoplasma* spp., and *T. whipplei* (Raoult et al. 1996; Brouqui and Raoult 2001; Fenollar et al. 2003; Houpikian and Raoult 2003). Although specialized culture techniques are available for some of these obligate intracellular pathogens in certain reference laboratories, most laboratories will still rely on serological diagnosis. Blood cultures also remain negative in over 50 percent of cases of fungal endocarditis such as that caused by *Aspergillus* spp. (Rubinstein et al. 1975).

An incorrect diagnosis of infective endocarditis based on a false interpretation of clinical or echocardiographic

findings may also be the reason for an apparently *culture-negative* endocarditis. This is probably quite common since physicians are rightly concerned not to miss a case of infective endocarditis.

In conclusion, in all cases of defined or suspected endocarditis with negative blood cultures in the absence of previous antimicrobial therapy serum should be analyzed for *Bartonella*, *Coxiella*, and *Chlamydia* species antibodies, and the excized valve should be analyzed by microscopy, culture, and histology. In addition, specialized culture techniques and relevant PCR techniques might be attempted at a reference laboratory (see below).

Clinical manifestations and complications

The clinical presentation of infective endocarditis is determined by the local infection of the valve and its complications, the occurrence of septic embolization of valvular vegetations to distant organs, constant bacteremia that may result in distant foci of infection, and the consequences of circulating immune complexes. The symptoms and signs of infective endocarditis are therefore extremely variable (Table 6), and the differential diagnosis is broad.

Fever is the most common sign but may be absent in severely compromised patients, patients with chronic renal or hepatic failure, infective endocarditis with less virulent organisms and in particular with previous antimicrobial therapy. Fever usually abates within 3–7 days of appropriate antimicrobial treatment, but prolonged fever may be associated with major intracardiac or embolic complications, such as myocardial or splenic abscess, and should therefore prompt further diagnostic evaluation. Nonspecific findings seen especially in subacute cases of infective endocarditis include weight loss, weakness, anorexia, malaise, nausea, and night sweats.

Most patients with infective endocarditis have a heart murmur, that may rarely present as the classic *changing murmur* or *new regurgitant murmur*, but in most cases is a pre-existing murmur. Other classical peripheral findings include splinter hemorrhages (Figure 2), i.e. red to brown streaks below the finger nails or toe nails, petechiae on the skin, the conjunctivae, and oral mucosa that both result from local vasculitis or emboli, and the only rarely seen Osler nodes, small, painful subcutaneous nodular lesions found in the pulp of the digits or in the thenar eminence. Janeway lesions are nontender, hemorrhagic or pustular lesions, often found on the palms and soles, also resulting from peripheral septic emboli (Figure 3). Janeway lesions consist of bacteria, neutrophils, necrosis, and subcutaneous hemorrhage and are

Table 6 *Signs and symptoms of infective endocarditis*

Sign/symptom	% of patients affected
Fever	80
Malaise	25
Chills	40
Weakness	40
Sweats	25
Anorexia/weight loss	25
Myalgia/arthralgia	15
Heart murmur	85
Changing or new murmur	3–10
Skin manifestations	15–30
Janeway lesions	<10
Osler nodes	1–23
Petechiae	20–40
Splinter hemorrhages	15
Roth spots	2–10
Splenomegaly	20–57
Embolic phenomena	>50

Figure 2 *Splinter hemorrhages are usually located under the finger or toe nails.*

Figure 3 *Janeway lesions are nontender, erythematous, hemorrhagic, or pustular lesions, often located on the palm or soles.*

often seen in staphylococcal endocarditis. The offending microorganisms may be readily cultured from these lesions. Roth spots are oval retinal lesions surrounded by hemorrhage occurring only in a minority of cases.

The complications of infective endocarditis have been reviewed recently by Mansur et al. (1992). The leading cardiac complication is congestive heart failure caused by a progressive infection-induced valvular destruction such as perforation of the valve leaflet, the cordae tendineae, or papillary muscle. Severe congestive heart failure was observed in 34 percent of patients with infective endocarditis in the French series (Hoen et al. 2002). Aortic-valve involvement is more frequently associated with congestive heart failure than is mitral-valve involvement in infective endocarditis. Other complications include rupture of the intraventricular septum, myocarditis or myocardial infarction resulting from coronary artery embolization or mycotic aneurysm, and myocardial and valve ring abscesses. Extension of the infection into the septum may cause arrhythmias and conduction abnormalities. Other distant complications mainly result from embolic events and metastatic infections (Millaire et al. 1997). Overall, vascular complications were seen in 44 percent of patients with infective endocarditis reported by Hoen et al. (2002), the vast majority of which were systemic arterial emboli.

Neurologic manifestations usually resulting from cerebral emboli occur in 20–40 percent of cases and often represent the dominating clinical syndrome, especially in staphylococcal endocarditis (Roder et al. 1997; Heiro et al. 2000). A stroke syndrome in a febrile patient with underlying valvular disease suggests the possibility of infective endocarditis. Cerebral manifestations include cerebral infarction, abscesses, intracerebral mycotic aneurysms, cerebritis, meningitis, and intracerebral or subarachnoid hemorrhage. Resulting symptoms encompass hemiplegia, aphasia, sensory loss, headache, seizures, and altered mental status, ranging from slight personality changes to frank psychosis.

Splenomegaly is common among patients with infective endocarditis and mostly seen in patients with prolonged disease. Splenic abscess may develop from bacteremic seeding of a previously infarcted area or directly from an infected embolus. Splenic abscess was among the rarer complications reported by Mansur et al. (1992) with clinical signs or symptoms often absent; this complication was observed in 10 percent of patients with infective endocarditis in the French series (Hoen et al. 2002). However, splenic septic emboli and infarction were reported in 44 percent of patients at autopsy (Weinstein and Schlesinger 1974). Prolonged fever and sepsis may be a clinical clue to this complication and should prompt ultrasound investigation, abdominal CT scan or MRI (Yilmaz et al. 2003).

Renal involvement includes infarction and abscess formation leading to bacteruria, as well as immune complex glomerulonephritis. Renal failure is mainly seen in long-standing disease, but is usually reversible with antimicrobial treatment (Conlon et al. 1998).

Musculoskeletal symptoms in infective endocarditis include diffuse myalgias, low back pain, arthalgia, and septic arthritis.

Mycotic aneurysms may result from direct bacterial invasion of the arterial wall with subsequent abscess formation and rupture, from embolic occlusion of the vasa vasorum, or immune complex deposition into the arterial wall. They are found most commonly at bifurcation points primarily of the cerebral vessels and are often clinically asymptomatic until perforation or rupture occurs. Major vessel emboli are rare in bacterial endocarditis and are more frequently encountered in fungal endocarditis (Pierrotti and Baddour 2002).

Right-sided endocarditis is not associated with peripheral emboli and other peripheral vascular phenomena. Instead, pulmonary findings are usually present, such as pulmonary embolism with and without infarction, pneumonia, pleuritic chest pain, pleural effusion, and empyema (Miro et al. 2003; Moss and Munt 2003). Community-acquired *S. aureus* bloodstream infection in the presence of multiple pulmonary infiltrates should always suggest right-sided infective endocarditis, and in the at-risk person intravenous drug abuse as well. Heart murmurs are frequently absent in right-sided endocarditis.

Diagnosis

DEFINITION OF DIAGNOSTIC CRITERIA

The diagnosis of infective endocarditis requires consideration of clinical, laboratory, and echocardiographic findings. To help the clinician to establish the diagnosis of infective endocarditis and to allow for comparison of published reports, attempts have been made to define hard diagnostic criteria. Von Reyn et al. (1981) introduced the categories of *definite*, *probable*, and *possible* IE but their 'definite' category relied on direct evidence from histology or microbiology at surgery or autopsy. The so-called Beth Israel criteria proved very specific, but less sensitive. Their *definite* category was too restrictive. Over a decade later with the advent and more common usage of echocardiography, Durack et al. (1994) proposed new criteria of *definite* and *possible* infective endocarditis based on a much more comprehensive assessment that included clinical and echocardiographic findings, and these have gained widespread acceptance. The so-called Duke criteria and their suggested modifications (Fournier et al. 1996; Lamas and Eykyn 1997; Li et al. 2000) are built on two major criteria, i.e. microbiologic criteria and clinical or echocardiographic evidence of endocardial involvement.

The microbiologic criteria include a positive blood culture for infective endocarditis as defined by the recovery of (1) a typical microorganism from two sepa-

rate blood cultures in the absence of a primary focus (i.e. 'viridans' streptococci, *S. bovis*, HACEK group, or community-acquired *S. aureus* or enterococci); (2) a persistently positive blood culture defined as the recovery of a microorganism consistent with endocarditis from either blood cultures drawn more than 12 h apart or all three or a majority of four or more separate blood cultures with the first and last drawn at least 1 h apart; or (3) serology for Q fever by IFA showing phase 1 IgG antibodies at >1:800.

Evidence of endocardial involvement includes a positive echocardiogram for infective endocarditis, i.e. (1) an oscillating intracardiac vegetation on valve or supporting structures, in the path of regurgitant jets, or on implanted material; (2) a periannular abscess; or (3) a new dehiscence of a prosthetic valve; or new valvular regurgitation on auscultation (increase or change in preexisting murmur is not sufficient).

Minor diagnostic criteria include (1) a predisposing cardiac condition – such as previous endocarditis, aortic-valve disease, rheumatic heart disease, prosthetic heart valve, complex congenital heart disease, and many others – or injection-drug use; (2) fever $\geqslant 38^{\circ}C$; (3) vascular phenomena such as major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, or Janeway lesions; (4) immunologic phenomena such as glomerulonephritis, Osler's nodes, Roth spots, or rheumatoid factor; and (5) microbiologic evidence such as a positive blood culture not meeting the major criteria or serologic evidence of an active infection with organism consistent with infective endocarditis, such as *Brucella* spp., *Chlamydia* spp., *Legionella* spp., and *Bartonella* spp.; and (6) echocardiographic findings consistent with infective endocarditis, but not meeting major criteria.

According to the Duke Endocarditis Service, the diagnosis of infective endocarditis is definite (1) when a microorganism is demonstrated by culture or histologic testing in a vegetation; (2) when active endocarditis is histologically confirmed at surgery or at autopsy; or (3) in the presence of two major criteria, one major and three minor criteria, or five minor criteria as outlined above (Durack et al. 1994).

The usefulness of the Duke criteria has been validated and compared to the von Reyn criteria in several subsequent studies (Bayer 1996; Martos-Perez et al. 1996; Heiro et al. 1998; Habib et al. 1999; Perez-Vazquez et al. 2000). Overall, the specificity of the proposed criteria was high (99 percent) and the negative predictive value greater than 92 percent.

MEDICAL HISTORY

The patient's medical history might be an important clue for the etiologic diagnosis of infective endocarditis. A history of contact with cattle or sheep may suggest infection caused by *C. burnetii* (Q fever) or *Brucella* species. Contact with a cat, in particular a history of scratches or bites, suggests *Bartonella henselae* or *Pasteurella* spp. Exposure to birds has been related to infection with *C. psittaci*. Further clues as to patients' medical history related to endocarditis can be found in the review by Brouqui and Raoult (2001).

LABORATORY FINDINGS

Unspecific laboratory findings are usually present in infective endocarditis, but none is diagnostic. Hematological parameters include anemia in 70–90 percent of cases and less often leukocytosis which is present in only 20 to 30 percent of cases of subacute endocarditis, but is more frequent in the acute form. The erythrocyte sedimentation rate (ESR) is elevated in 90–100 percent of cases, so that a normal ESR usually rules out the diagnosis of infective endocarditis. Similarly, the C-reactive protein (CRP) concentration is virtually always elevated. Serial determination of both parameters, ESR and CRP, are useful for monitoring antimicrobial therapy and may also be a diagnostic clue for the detection of clinically silent embolic complications.

ECHOCARDIOGRAPHY

Cardiac imaging, specifically echocardiography, has greatly enhanced the ability of clinicians to effectively diagnose and manage infective endocarditis. Echocardiograms should generally be obtained in all patients suspected of having infective endocarditis, both to establish the diagnosis and to identify complicated cardiac involvement that may warrant surgical intervention (Bayer et al. 1998). Manifestations of endocardial involvement include vegetations, abscesses, aneurysms, fistulae, leaflet perforations, and valvular dehiscence. Transthoracic echocardiography (TTE) is a noninvasive and rapid method with excellent specificity. The sensitivity however, drops to less than 60 percent in patients with obesity, chronic obstructive lung disease, and chest wall deformities. It has therefore been recommended to perform transesophageal echocardiography if TTE is inconclusive. Transesophageal echocardiography (TEE) is more invasive and also more expensive than TTE, but also more sensitive than the transthoracic approach (Shively et al. 1991; Chamis et al. 1999; Roe et al. 2000; Humpl et al. 2003) and currently represents the optimal approach to echocardiographic imaging. Initial use of TEE is more cost-effective and diagnostically efficient in all patients with an intermediate or high pretest probability of infective endocarditis, particularly in the setting of prosthetic valves (Heidenreich et al. 1999). In a prospective study of patients with *S. aureus* bacteremia, Fowler and colleagues (1997) reported that sensitivity of TTE for detecting infective endocarditis was 32 percent, and the specificity was 100 percent. The addition of TEE increased the sensitivity to 100 percent,

but resulted in one false-positive result (specificity 99 percent). Echocardiographic imaging has also been used to guide therapeutic management of patients with infective endocarditis (Harris et al. 2003; Kim et al. 2003). TEE is especially useful for detecting perivalvular extension of infective endocarditis and the presence of an intramyocardial abscess, as well as for evaluation of prosthetic-valve endocarditis.

CULTURE METHODS

The blood culture is the single most important method applied in the diagnostic work-up for infective endocarditis. The bacteremia in patients with culture-positive endocarditis is usually continuous and low-grade. The application of quantitative blood culture techniques has demonstrated that between one and 10 bacteria per ml are present in the blood of patients with infective endocarditis and this bacterial density remains constant during the entire course of the untreated disease (Werner et al. 1967). The details of taking blood cultures have been presented elsewhere in this chapter. It has been recommended that at least 10 ml of blood be obtained for each culture and that at least three blood cultures sets (no more than two bottles per venipuncture) are obtained in a patient with suspected endocarditis (Washington 1982, 1987). If clinical conditions permit, blood cultures should be drawn at least 1 h apart. In cases where the institution of antimicrobial therapy can be postponed for 24 h, another three blood cultures should be obtained the following day. More blood cultures may be necessary if the patient has received antimicrobials in the preceding 2 weeks. Blood cultures should be incubated for at least 3 weeks. An evidence-based approach for sequential testing in infective endocarditis has recently been proposed by Watkin et al. (2003).

If no previous antimicrobial therapy was administered and blood cultures remain negative in a patient with probable or definite endocarditis on clinical or echocardiographic grounds, i.e. culture-negative endocarditis by definition, fastidious organism should be suspected, and special cultivation methods be considered. The simplest approach to isolate *Abiotrophia* spp. is to inoculate the blood culture broth on to blood agar that is cross-streaked with *S. aureus* where these species grow as satellite colonies. Most members of the HACEK group and other fastidious organisms can be recovered after prolonged incubation of blood cultures for 3 to 4 weeks both with conventional, as well as with automated blood culture systems. Prolonged incubation is therefore recommended as a routine procedure in the diagnostic work-up of blood cultures from patients with suspected endocarditis. The isolation of rare pathogens such as *Legionella* spp., mycobacteria, and *Bartonella* spp. requires special techniques recently reviewed by Brouqui and Raoult (2001). These authors also have developed tissue cell cultures for the isolation of obligate intracellular pathogens such as *Bartonella* spp., *Chlamydia* spp., and *C. burnetii*.

Pathogens can also be cultured from resected valves or biopsy specimens by inoculation on to agar or into tissue culture. Histologic examination of resected valve material is mandatory, particularly in the case of culture-negative endocarditis. A discussion of the appropriate staining techniques and immunohistological methods is beyond the scope of this chapter.

SEROLOGY

The most common serologic methods applied to the microbiological diagnosis of infective endocarditis include indirect immunofluorescence for *B. henselae*, the tube agglutination test for *Brucella melitensis* infections, ELISA or indirect immunofluorescence for *Chlamydia* spp., indirect immunofluorescence for *C. burnetii* and *Legionella* spp., and ELISA for *Mycoplasma pneumoniae*. Systematic serologic testing for these organisms is particularly warranted in cases of clinically suspected culture-negative infective endocarditis (Houpikian and Raoult 2003). Among 19 cases of culture-negative endocarditis in the French series, eight microorganisms were identified by serological methods: *Bartonella* spp. ($n = 3$), *C. burnetii* ($n = 1$), *Legionella* spp. ($n = 1$), *Chlamydia* spp. ($n = 2$), and *M. pneumoniae* ($n = 1$).

MOLECULAR METHODS

The advent of molecular amplification methods has enlarged the spectrum of nonculture laboratory methods for the diagnosis of infective endocarditis (Fournier and Raoult 1999; Lisby et al. 2002). Such techniques have been applied to most types of clinical materials including blood and valvular specimens obtained at surgery (Grijalva et al. 2003) or autopsy. Broad-range PCR that incorporates broad-spectrum primers targeting bacterial 16S rRNA allows for the detection of almost all bacteria in a single reaction. This method combined with sequence analysis of the amplified DNA has proved to be a promising tool for patients with culture-negative endocarditis (including instances of prior antimicrobial treatment) and allows the detection of rare, noncultivable organisms (Bosshard et al. 2003). Such novel approaches may lead to more comprehensive patient evaluations and the discovery of new etiologic agents of infective endocarditis. It has therefore been suggested to include positive identification of an organism by molecular biology methods as an additional major criterion in the revised Duke criteria of infective endocarditis (Millar et al. 2001; Bosshard et al. 2003).

In contrast to its use directly on clinical samples, PCR with subsequent sequencing of the amplification product can also be used for identification of bacteria isolated by culture methods in cases when species identification proves difficult by conventional biochemical methods. Such techniques clearly have increased the identification

of rare and fastidious microorganisms recovered from patients with infective endocarditis in recent years.

PROSTHETIC VALVE ENDOCARDITIS

Prosthetic valve endocarditis (PVE) is an uncommon but potentially disastrous complication of cardiac valve replacement. It accounts for 7 to 25 percent of cases of infective endocarditis in most developed countries (Vlessis et al. 1997; Mylonakis and Calderwood 2001; Hoen et al. 2002). The risk of an individual patient developing PVE at any particular time is difficult to determine from reported studies of PVE. As Rutledge et al. (1985) pointed out, to cite a frequency of PVE of 4 percent as many studies do is not very valuable, since the risk of developing PVE is not uniform over time; it is higher during the initial 6 to 12 months after surgery and subsequently decreases. It has been estimated that the cumulative risk developing PVE ranges between 3 and 6 percent by 5 years after surgery (Ivert et al. 1984; Calderwood et al. 1985; Rutledge et al. 1985; Agnihotri et al. 1995). The rate of PVE was higher for recipients of a mechanical valve during the initial 3 months after surgery compared to patients with a bioprosthetic valve, but after 12 months the risk of infection was greater for the latter group (Calderwood et al. 1985). It appears that patients with a prosthetic heart valve carry a life-long risk of acquiring PVE.

PVE has conventionally been considered as *early* and *late*, with 60 days regarded as the time limit for early cases (Dismukes et al. 1973) because of differences between the microbiology and pathogenesis of infection in the two time periods. Early PVE results from perioperative contamination, as well as from bacteremia arising during the early postoperative period, and is thus usually a hospital-acquired infection (Gordon et al. 2000). Early after valve replacement the intracardiac structures involved in the operation are not endothelialized and therefore especially vulnerable to the deposition of fibrin platelet aggregates and subsequent bacterial colonization. Not all these 'early' infections present within 60 days of operation and this has led some investigators to suggest that the time limit for early disease should be extended to 6 months or even a year. PVE occurring later than 12 months after valve replacement is more likely to result from transient community-acquired bacteremia, such as is the case with community-acquired native valve endocarditis. Whatever classification is used, it is clear that the causative microbes of PVE acquired in hospital and the severity of disease differ from PVE acquired in the community, often many years after valve replacement.

The incidence of early PVE has fallen since the advent of valve replacement surgery over 40 years ago, but the most common infecting organisms are still likely to be staphylococci, both coagulase-negative staphylococci (mostly *S. epidermidis*) and *S. aureus*, followed by gram-negative bacilli, enterococci, corynebacteria, and fungi (Wolff et al. 1995). Coagulase-negative staphylococci account for approximately 30 percent of cases. These are skin organisms and may arise both from the patient's own commensal flora, as well as from health care personnel. Interestingly, the majority of these strains are methicillin-resistant (Calderwood et al. 1985).

The pathogenesis of late PVE differs from that of early PVE and is similar to that of native valve endocarditis with bacteria from the bloodstream localizing on the prosthesis or damaged endocardium. As with community-acquired native valve endocarditis, the most common pathogens in late PVE are streptococci, enterococci, and staphylococci, but a larger percentage of cases than in native valve disease are caused by coagulase-negative staphylococci.

Typical features of PVE are large vegetations, embolic complications, and invasive infection extending into the annulus and adjacent myocardium resulting in paravalvular abscess formation and valve dehiscence (Graupner et al. 2002). Invasive infection has been associated with clinical findings of valvular dysfunction, persistent fever despite appropriate antimicrobial therapy, and echocardiographic evidence of abscess formation. Invasive infection is more commonly observed during the first 12 months after surgery.

The Duke criteria, primarily established for the diagnosis of native valve infective endocarditis can also be applied for the diagnosis of PVE (Nettles et al. 1997; Perez-Vazquez et al. 2000). Diagnosis mainly relies on blood cultures and echocardiographic findings. Blood cultures must be obtained frequently and in the absence of antimicrobial therapy, in particular in the febrile postoperative patient. This is of particular importance related to the fact that the organisms most frequently involved in early PVE, i.e. coagulase-negative staphylococci and diphtheroids, are also the most frequently encountered contaminants of blood cultures. The superiority of TEE in comparison to TTE relates to the increased diagnostic sensitivity in detecting periprosthetic leaks, abscesses, and fistulas (Lengyel 1997; Bach 2000; Greaves et al. 2003).

The mortality of PVE is high, particularly in patients with onset of infection within 2 months of surgery and if infection is caused by *S. aureus* (Wolff et al. 1995). Other predictors of mortality are severe congestive heart failure and signs of invasive disease such as persisting fever, despite appropriate antimicrobial therapy. Mortality rates as high as 77 percent have been described in earlier series (Dismukes et al. 1973). Mortality rates ranging from 10 to 30 percent have been observed in more recent surveys, where earlier surgery may have contributed to a more favorable outcome (Akowuah et al. 2003). Overall, 40 to 65 percent of patients with PVE may be candidates for surgical intervention (Lytle et al. 1996; Fowler et al. 1998). Patients that may be treated by medical therapy alone are those with late-onset infection, with infection

caused by less virulent organisms, and those without evidence of invasive disease. The mortality of late PVE is less than that of early infection and not much different than for native valve infection. Patients with late PVE are likely to present to doctors earlier than many of those with native valve infection and hence to be referred to specialist departments earlier. Both these factors are relevant to outcome.

TREATMENT OF INFECTIVE ENDOCARDITIS

In the pre-antibiotic era, infective endocarditis was almost uniformly fatal and no-one can deny that antibiotics have dramatically reduced the mortality of the disease. Antimicrobial therapy should consider some specific conditions in infective endocarditis that are unique among bacterial infections, i.e. the infection involves an area of impaired host defense – the vegetation – with bacteria embedded in a fibrin meshwork where they are sheltered from phagocytic cells, where the bacteria reach enormous population densities, and where they may exist in a state of reduced metabolic activity. Therefore certain general treatment principles should be followed: (1) high-dose parenteral antimicrobial therapy is recommended to reach sustained antibacterial activity; (2) prolonged administration of antimicrobial therapy is necessary to prevent relapse; (3) bactericidal antimicrobial agents are generally preferred over bacteriostatic drugs; (4) antibiotic combination therapy is recommended to produce a rapid bactericidal effect (Le and Bayer 2003). Unless the patient is very unwell, toxic, and septic, antibiotics should preferably be withheld until the blood culture results are available. Many patients with infective endocarditis will have been ill for several weeks or even months, and thus a delay of 1–2 days in starting antibiotics cannot make any difference to the course of the disease.

Wilson et al. (1995) have recently reviewed the treatment of infective endocarditis due to streptococci, enterococci, staphylococci, and fastidious organisms of the HACEK group. Detailed guidelines are also given in the report from the Working Party in Endocarditis of the British Society for Antimicrobial Chemotherapy (BSAC) which has recently been updated (1998).

The recommended approach to 'penicillin-sensitive' streptococcal native valve endocarditis (i.e. oral streptococci and group D streptococci including *S. bovis* with a minimum inhibitory concentration (MIC) for penicillin $\leqslant$0.1 mg/l) consists of administration of aqueous penicillin G, 10–30 million units IV daily, or ceftriaxon, 2 g once daily IV or IM, for 4 weeks. The addition of gentamicin to penicillin exerts a synergistic killing effect on viridans streptococci in vitro and results in more rapid sterilization of cardiac vegetations in an animal model of endocarditis, but has not reached clinical cure rates superior to those obtained with penicillin alone in clinical studies. Short-course therapy of penicillin combined with gentamicin (3 mg/kg IV divided into three daily doses) for 2 weeks has been advocated in uncomplicated cases with comparable cure rates as high as 98 percent. This approach is not recommended for patients with myocardial abscess, embolism, or extracardiac metastatic foci of infection, and impaired renal function. In patients with prosthetic valve endocarditis a 6-week regimen of penicillin together with gentamicin for the first 2 weeks is recommended. Vancomycin therapy, 1 g IV twice daily for 4 weeks is indicated for patients with confirmed immediate hypersensitivity reactions to betalactam antibiotics.

Endocarditis due to viridans group streptococci with an MIC for penicillin >0.1 to 0.5 mg/l usually requires a 4-week course of penicillin together with gentamicin for the first 2 weeks. For patients with endocarditis with viridans streptococci with an MIC for penicillin >0.5 mg/l and nutritionally variant streptococci treatment with the regimen recommended for enterococcal endocarditis is advised (see below).

Enterococci are less susceptible to betalactam antimicrobial agents than streptococci (median MIC for penicillin: 2 mg/l), and in general these agents are bacteriostatic against the enterococci; combination regimens are therefore always recommended for treating enterococcal endocarditis. Cell wall-active antibiotics, such as beta-lactams or glycopeptides plus an aminoglycoside, are synergistic and exert a bactericidal effect in vitro against most enterococci unless high-level resistance to gentamicin (MIC >500 mg/l) or streptomycin (MIC >2 000 mg/l) is present. In these cases, penicillin- or vancomycin-aminoglycoside synergy and bactericidal activity is not apparent. The standard antimicrobial recommendation for enterococcal endocarditis is penicillin (20–30 million units daily) or ampicillin (12 g daily) combined with gentamicin (3 mg/kg per day) administered IV for 4–6 weeks. The 6-week regimen is recommended for patients with duration of symptomatic illness exceeding 3 months, as well as for complicated and prosthetic valve endocarditis. In patients allergic to beta-lactams or infected with penicillin-resistant strains such as *E. faecium*, vancomycin is administered in combination with gentamicin. If endocarditis is caused by a strain exhibiting high-level aminoglycoside resistance, the addition of an aminoglycoside is no longer beneficial, and therapy should be prolonged to 8–12 weeks instead. However, clinical cure is often not obtained without valve replacement. Endocarditis due to vancomycin-resistant enterococci (VRE) is a cause of concern, and the antimicrobial regimen of choice for these cases remains unsettled.

The great majority of staphylococci, acquired either in the hospital or in the community, produce β-lactamase, and they are highly resistant to penicillin. The current recommended regimen for treatment of native valve staphylococcal endocarditis includes a penicillinase-resistant penicillin, nafcillin or oxacillin, 12 g daily IV, or

cefazolin (or another first generation cephalosporin), 6–8 g daily IV, given for 4–6 weeks. The addition of gentamicin induced a synergistic killing effect both in vitro and in an animal model of endocarditis and has also been shown to result in more rapid clearing of bacteremia from the bloodstream in patients. Many authorities therefore recommend the addition of gentamicin for the first 3–5 days of therapy, although the combination did not improve the survival rate in a clinical study involving a small group of patients. In the patient allergic to penicillin or when the isolate is methicillin-resistant (MRSA or MRSE in the case of *S. epidermidis*), vancomycin, 1 g twice daily IV for 4–6 weeks is the agent of choice. However, vancomycin is less rapidly bactericidal than nafcillin in vitro against *S. aureus*, and prolonged bacteremia and increased failure rates have been associated with the use of this agent in infective endocarditis caused by MRSA. Accordingly, caution is advised when considering treatment with vancomycin only for reasons of convenience related to pharmacokinetics such as in hemodialysis patients where once weekly administration of vancomycin is possible. Although routine use of rifampin in native valve endocarditis is not recommended, it has been used, however, as supplemental therapy for patients who did not respond to conventional antimicrobial therapy or those with suppurative complications, such as valve ring abscess, intracerebral abscess formation, and meningitis. However, the adjunctive role of rifampin remains controversial.

Staphylococcal endocarditis in the presence of intracardiac prosthetic material is most often caused by coagulase-negative staphylococci that are usually resistant to methicillin. In these cases, vancomycin and rifampicin are administered for 6 weeks combined with gentamicin for the first 2 weeks of therapy. If the organism is susceptible to methicillin, nafcillin or oxacillin in combination with rifampin and gentamicin is advocated. Based on the experimental finding that rifampin results in the complete sterilization of foreign bodies infected with *S. aureus*, a similar combination therapy of nafcillin or oxacillin in combination with rifampin and gentamicin is also considered the regimen of choice for prosthetic valve endocarditis due to methicillin-susceptible *S. aureus*. If strains are resistant to methicillin or the patient is allergic to penicillin, vancomycin is substituted for the penicillinase-resistant penicillin. If the organism is resistant to gentamicin, another third agent should be chosen based on in vitro susceptibility testing since staphylococci may become resistant to rifampin during combination therapy of prosthetic valve endocarditis.

Treatment options for endocarditis caused by fastidious gram-negative bacilli of the HACEK group include the administration of ampicillin (12 g daily) combined with gentamicin (3 g/kg per day) administered IV for 4 weeks, or preferably ceftriaxone to cover β-lactamase producing strains, 2 g daily for 4 weeks. Therapy should be extended to 6 weeks in the case of prosthetic valve endocarditis.

Treatment regimens for endocarditis caused by less common pathogens such as gram-negative enteric bacilli, *Brucella* and *Bartonella* spp., *C. burnetii*, *Legionella* spp., obligate intracellular pathogens, and fungi is still not adequately defined, and the readers are referred to the most recent review articles for details (Bayer et al. 1998; Brouqui and Raoult 2001; Mylonakis and Calderwood 2001).

The choice of antibiotics for the treatment of infective endocarditis is governed by the susceptibility of the causative organism. Determination of the minimum inhibitory concentration is recommended to define optimal treatment, while standard disk sensitivity testing is unreliable. The determination of the minimum bactericidal concentration (MBC), as well as performance of the serum bactericidal titer (SBT) test is not routinely advocated, the latter correlating poorly with clinical outcome. Since adverse events are rather frequent during prolonged antimicrobial therapy, it is often necessary to revise therapy. For additional testing, the causative organism should therefore be retained in the laboratory until cure has been achieved.

Several studies suggest that combined medical and surgical therapy for infective endocarditis can improve outcome. A major reduction in mortality followed the introduction of valve replacement surgery some 40 years ago, and even a further decline in mortality observed in some of the most recent surveys has been associated with earlier valve replacement and more refined surgical techniques (Cabell et al. 2002; Hoen et al. 2002). Currently, surgical intervention during treatment is required in 25–30 percent of patients with infective endocarditis. The generally accepted indications for surgical intervention during active infective endocarditis include (1) refractory congestive heart failure; (2) more than one serious embolic event; (3) uncontrolled infection or sepsis despite maximal antibiotic therapy; (4) significant valve dysfunction, perforation or rupture as demonstrated by echocardiography; (5) ineffective antimicrobial therapy (e.g. as in Q fever endocarditis, fungal endocarditis, and enterococcal endocarditis caused by high-level gentamicin- or vancomycin-resistant enterococci); (6) local suppurative complications including periannular extension of the infection, perivalvular or myocardial abscess; and (7) most cases of prosthetic valve endocarditis caused by antibiotic-resistant pathogens such as MRSA, gram-negative enteric bacilli, and *P. aeruginosa*. The optimal time for surgical intervention is before severe hemodynamic compromise or extension of the infection to adjacent tissue has occurred. Medical and surgical management decisions can be guided by echocardiographic detection of abscesses, prosthetic valve dehiscence, valvular dysfunction, and obstructive vegetations. If there is evidence of active endocarditis at the time of valve replacement

surgery based on a culture-positive vegetation or histologic evidence of significant polymorphonuclear inflammation, antibiotic therapy should be continued for at least several weeks. Excellent reviews on the indications for surgery during therapy for infective endocarditis are available (Moon et al. 1997; Bayer et al. 1998; Alexiou et al. 2000; Delay et al. 2000; Guerra et al. 2001; Olaison and Pettersson 2003).

PREVENTION OF ENDOCARDITIS

Since infective endocarditis is a disease with significant morbidity and mortality, its prevention is a laudable objective, but how best to achieve this, or indeed whether it can be achieved, is another matter. A variety of preventive measures could theoretically be used to interrupt the sequence of events that finally results in endocarditis. These include elimination or treatment of predisposing conditions, elimination of portals of entry for organisms, e.g. by maintaining good oral hygiene, immunization against bacteria that cause endocarditis, and administration of antibiotics during high risk procedures. Of these, administration of antibiotics has received the most attention. There are numerous national guidelines for prophylaxis and these vary both in their antibiotic regimens and in the range of procedures for which prophylaxis is required. Over the past decade, however, there has been some uniformity of recommendations both within Europe and elsewhere. The diversity of the recommendations serves to emphasize the lack of critical data on which to base them. A detailed discussion of antimicrobial prophylactic strategies is beyond the scope of this chapter, and readers are referred to the above-mentioned guidelines (Simmons 1993; Leport et al. 1995; Dajani et al. 1997).

The guidelines for the prevention of late PVE are essentially the same as those outlined for endocarditis on native valves though some differentiate between the regimens for the two groups (Hyde et al. 1998; Segreti 1999). The prevention of early PVE concerns prophylactic antibiotics at the time of valve replacement. This has been a controversial issue for many years and has been plagued by many small poorly conducted trials. The available evidence suggests that antibiotic prophylaxis reduces the postoperative wound infection in cardiothoracic surgery in general (Kreter and Woods 1992) and, by inference, in valve replacement surgery in particular. It is assumed, though never proved, that a reduction in wound infection will equate with a reduction in PVE and this seems a reasonable assumption. Various antibiotics are used and no single regimen has been shown to be superior. The increasing prevalence of methicillin-resistant staphylococci in hospitals, both *S. aureus* (MRSA) and coagulase-negative staphylococci, has led many to use vancomycin rather than cefazolin and cefuroxime which are the most cost-effective agents for perioperative prophylaxis. However, this issue remains controversial.

Bacterial meningitis

KEITH A.V. CARTWRIGHT

Introduction	1	Pneumococcal meningitis	15
Pathophysiology	1	Neonatal meningitis	20
Clinical features	3	Tuberculous meningitis	21
Diagnosis of meningitis	3	Other types of bacterial meningitis	21
Meningococcal disease	6	References	21

INTRODUCTION

More than 2 000 cases of bacterial meningitis, with at least 150 deaths, are notified each year in the UK and similar incidence data are reported by many other countries. The emphasis in this chapter will be on the epidemiological, pathophysiological, and diagnostic aspects of the disease. Fuller accounts of the key organisms can be found in *Streptococcus* and *Lactobacillus*; 37, *Listeria*; 48, *Neisseria*; and 65, *Haemophilus*. The various clinical syndromes are well described in Lambert (1991)).

In meningitis, the membranes that surround the brain and spinal cord become inflamed. Most meningitis is viral, usually with mild illness, but viral and bacterial meningitis may be confused (Maxson and Jacobs 1993).

The commonest cause of bacterial meningitis worldwide is *Neisseria meningitidis*, the meningococcus. In unimmunized populations, capsulate strains of *Haemophilus influenzae* type b (Hib) may cause as many, or more cases, especially in young children. *Streptococcus pneumoniae* and *Mycobacterium tuberculosis* rank next in order of frequency. Many other microbes and organisms, including bacteria, fungi, protozoa, and worms, may also cause meningitis or meningeal inflammation.

In neonatal meningitis, group B streptococci and *Escherichia coli* predominate, whereas *Listeria monocytogenes* causes meningitis in neonates, during pregnancy, and in old age. Fungal meningitis is particularly associated with severe immunosuppression as in the late stages of human immunodeficiency virus (HIV) infection. Many other bacteria, including staphylococci (Jensen et al. 1993), coliforms, and environmental gram-negative bacilli such as *Pseudomonas aeruginosa* and *Acinetobacter* spp. (Siegman-Ingra et al. 1993), occasionally cause meningitis, often in associations with inpatient hospital care, severe immunosuppression, neurosurgery, cranial trauma, infection of cerebrospinal fluid (CSF) reservoirs or shunts.

In economically advanced countries, the mortality from bacterial meningitis is less than 10 percent but it may be 30 percent or more in developing countries (Greenwood 1987; Bryan et al. 1990; Bijlmer 1991). The epidemiology is changing swiftly following the development of conjugated polysaccharide vaccines for invasive Hib disease, for meningococcal meningitis caused by serogroups A, C, Y, and W-135, and for pneumococcal meningitis caused by a range of common serotypes. In the UK, following the control of serogroup C meningococcal disease through vaccination, there are now good prospects for further reductions in the incidence of bacterial meningitis in the near future, particularly if serogroup B meningococcal vaccines can be developed, but also if the incidence of pneumococcal meningitis can be reduced through vaccination (Figure 1).

PATHOPHYSIOLOGY

The evolution of bacterial meningitis follows a sequence of exposure to the pathogen, acquisition, and then invasion. Invasion can be subdivided into three processes: mucosal penetration is followed by invasion of the

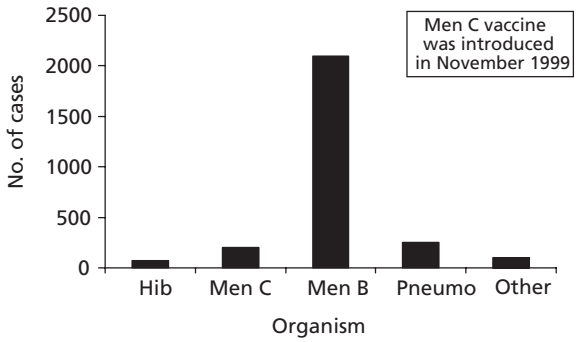

Figure 1 *Estimated incidence of bacterial meningitis and meningococcal disease in the UK, end 2002.*

bloodstream and then invasion of the meninges (Tunkel and Scheld 1993). The human nasopharynx is the natural habitat of the meningococcus, Hib, and the pneumococcus. Exposure is more frequent than acquisition, which is more frequent than bloodstream invasion. Understanding the process of establishment of bacterial meningitis has been greatly assisted by the development of animal models of infection (O'Donoghue et al. 1974; Moxon et al. 1977; Tauber and Zwahlen 1994).

Exposure

Exposure depends on the frequency and intimacy of interactions between colonized and susceptible individuals, the capacity of colonized individuals to disseminate bacteria from the nasopharynx, and the capacity of others around them to become colonized. Surprisingly little is known about these aspects, but dissemination may be influenced by the intensity of colonization, intercurrent viral infections (Gwaltney et al. 1975), and perhaps the ambient temperature and humidity.

Acquisition

Carriage rates reflect both acquisition rates and the duration of carriage. The duality is important; much evidence suggests that if bacterial invasion is to occur, it follows very shortly after acquisition. Individuals colonized for weeks or months are unlikely to develop invasive disease, though anecdotes do exist to show that invasion may sometimes follow weeks after acquisition and colonization (Neal et al. 1999).

With increasing age, the nasopharynx becomes progressively less susceptible to colonization by meningococci, Hib, and pneumococci. This may be due to the development of mucosal immunity.

Mucosal invasion

Bacterial strains vary greatly in their capacity to invade. Meningococci that do not express a capsule are essentially avirulent, while strains of serogroups A, B, and C are more invasive than strains of serogroups X, Y, and W-135 and other groups of meningococci (see *Neisseria*). Similarly, acapsulate strains of *H. influenzae* have little invasive potential, and though there are six capsular serotypes of *H. influenzae*, type b strains account for more than 95 percent of all invasive hemophilus disease in unimmunized populations.

The interaction of bacteria with the nasopharyngeal mucosa and other tissues has been investigated with tissue explants (Stephens and Farley 1991; Read et al. 1995), cultured epithelial and endothelial cells (Virji et al. 1991; Pujol et al. 1997), and the use of bacterial transformants and microarray technology (Grandi 2001). This has allowed comparisons between the behavior of fully virulent bacteria and strains that differ from them by the deletion of single genes or operons.

Capsulate meningococci bind to epithelial cells by adhesins, including fimbriae and the Opc outer-membrane protein (Virji et al. 1991, 1992). They cross the mucosal barrier by direct invasion of epithelial cells (endocytosis), whereas Hib strains migrate between epithelial cells by breaking down intercellular tight junctions (Stephens and Farley 1991). Once in the submucosa, the invading bacteria cross the capillary vessel basement membrane and the endothelium to gain access to the bloodstream.

The three major bacterial meningitis pathogens produce an IgA1 protease, whereas closely related nasopharyngeal 'commensals,' such as *Haemophilus parainfluenzae*, *Neisseria lactamica*, and viridans streptococci, do not (Mulks and Plaut 1978; Mulks 1985). Invasion potential and production of IgA1 protease (and the converse) are so closely associated that a causal relationship has long been sought. One hypothesis is that circulating IgA may block binding sites that would otherwise be accessible to lethal, bacteriolytic complement-fixing IgG or IgM antibodies (Griffiss 1982). Bacteria that invade may be further protected by cleavage of the blocking immunoglobulin molecules by IgA protease.

Respiratory viral infections may play a part in precipitating bacterial meningitis (Rolleston 1919; Krasinski et al. 1987; Moore et al. 1990; Scholten et al. 1999), in particular influenza A, which increases both the risk (Cartwright et al. 1991) and the severity (Hubert et al. 1992) of meningococcal disease. The mechanism in this latter situation is probably postviral immune suppression.

Meningeal invasion

Normal CSF contains few phagocytic cells and very low levels of complement and antibody; the normal CSF:blood IgG ratio is about 1:800. The integrity of the normal blood–brain barrier, and thus of the subarachnoid space, is maintained by a combination of tight intercellular junctions between capillary endothelial cells

of the cerebral microvasculature and by the comparative rarity of pinocytosis by these cells.

The cerebral capillary endothelium of the choroid plexus can bind some of the bacteria that cause meningitis. Bound bacteria may then undergo fimbrial phase variation in order to cross the blood–brain barrier (Saukkonnen et al. 1988). Bacteria may also gain access to the subarachnoid space within host phagocytic cells (Tunkel and Scheld 1993; McNeil et al. 1994).

Once bacteria are established within the subarachnoid space they are transiently sheltered from the host defenses. They can release substances capable of disrupting the blood–brain barrier. In the CSF, *H. influenzae* type b lipopolysaccharide (an endotoxin) rapidly induces the production of inflammatory cytokines, including interleukin-1 and tumor necrosis factor. Pneumococcal cell walls, which contain peptidoglycan and teichoic acid, are more potent than capsular polysaccharide in inducing subarachnoid inflammation (Tuomanen et al. 1985). High CSF cytokine concentrations are reached within 1–2 h of the arrival of bacteria in the CSF (Tunkel and Scheld 1993; Spellerberg and Tuomanen 1994).

Disruption of the blood–brain barrier occurs as a result of breakdown of the intercellular tight junctions of the cerebral microvascular epithelium, permitting an influx of larger molecules from the bloodstream and migration of phagocytic cells into the CSF.

Factors predisposing to bacterial meningitis

Many factors predispose to bacterial meningitis, including age, male gender, winter season, exposure to smokers and smoking, low socioeconomic status, and (probably) stress (Stanwell-Smith et al. 1994). Contact with a case confers a substantially increased risk of meningococcal disease (de Wals et al. 1981; Cooke et al. 1989), though less so for *H. influenzae* meningitis; in contrast, pneumococcal meningitis is not normally regarded as a transmissible infection and clusters of cases of any form of invasive pneumococcal disease (including meningitis) are rare.

Host genetic factors that confer increased susceptibility to bacterial meningitis or to a poor outcome are increasingly the subject of investigation in the context of new investigative methods now becoming available (Hill 2001). This is an area where much information will accrue over the next few years. Specific host factors conferring susceptibility to meningococcal disease are addressed in the relevant section of this chapter.

CLINICAL FEATURES

The presenting features of meningitis are determined largely by the age of the patient and, to a lesser extent, by the causative organism and the route by which it has reached the meninges. In the great majority of cases, the early signs and symptoms are nonspecific. Fever, lassitude, malaise, muscular aches and pains, nausea, vomiting, and headache occur in both viral and bacterial meningitis but are more commonly due to the former. Identification of the symptoms that may give warning of impending serious illness can be very difficult. In temperate countries, the difficulty is compounded by the fact that influenza, viral respiratory infections, and bacterial meningitis all peak in the winter months. Specific symptoms that should immediately raise the suspicion of bacterial meningitis include photophobia, neck stiffness, drowsiness, and fitting. Fever accompanied by pallor, inconsolable crying, a fit, or any evidence of decreased consciousness in a febrile infant or young child are highly suspicious and should warrant immediate careful investigation. The anterior fontanelle may bulge as meningitis progresses in infants.

As bacterial meningitis develops, symptoms become more severe; most patients with bacterial meningitis are much iller than those with viral infections. The highest attack rates of bacterial meningitis are in infants and very young children who cannot give a verbal account of their symptoms. Familiarity with the symptoms, repeated examinations, and a high index of suspicion are the best safeguards for parents and family doctors. The combination of fever and a vasculitic rash (petechiae or purpura), which may herald meningococcal disease, constitutes a medical emergency. Meningococcal septicemia may occasionally progress so rapidly that patients can become moribund within 4–6 h of the first symptoms.

In contrast, tuberculous and fungal meningitis more commonly develop insidiously over days, weeks, or even months.

DIAGNOSIS OF MENINGITIS

Cerebrospinal fluid

LUMBAR PUNCTURE

Examination of CSF has long been considered as routine in the investigation of suspected bacterial meningitis (Gray and Fedorko 1992) but is not without its dangers and drawbacks, especially ‘coning’ (Rennick et al. 1993). If intracranial pressure is raised, lumbar puncture may occasionally be followed by herniation of the tentorium through the *falx cerebri* or of the brain stem through the *foramen magnum* (coning); either may be a fatal event or may lead to catastrophic neurological morbidity. Papilloedema is an insensitive indicator of raised intracranial pressure and clinicians will normally be wary of lumbar puncture in patients with evidence of diminished consciousness or fluctuating neurological status. A computed tomography (CT) scan is helpful in

determining whether there is raised intracranial pressure but does not provide absolute assurance of safety to proceed with lumbar puncture. An increasing proportion of pediatric patients with clinical evidence of meningitis are now managed without lumbar puncture (Cartwright and Kroll 1997; Wylie et al. 1997; Nadel 2001), though the procedure is still recommended in suspected meningitis in adults (Begg et al. 1999) because of the wider range of potential pathogens.

Despite the hazards, examination of CSF still offers the best chance of observing, isolating, and identifying the causative organism in bacterial meningitis (Kaplan et al. 1986b; British Society for the Study of Infection Research Committee 1995). Lumbar puncture is particularly valuable if a dose of a parenteral antibiotic has been given either before or on hospital admission, but if indicated, must be done swiftly, since cultures, even of CSF, rapidly become negative; CSF sterilization times of 2 h for meningococci and 4 h for pneumococci have been suggested (Kanegaye et al. 2001). Even if bacteria cannot be recovered on culture, microscopy is likely to confirm the diagnosis of bacterial meningitis and may indicate the likely causative organism. Lumbar puncture should never be used as a reason to defer commencing antibiotic treatment and other resuscitation measures. The 'door-to-needle' time for patients hospitalized for suspected bacterial meningitis should be less than 1 h.

Polymerase chain reaction (PCR) tests of CSF for the common bacterial meningitis pathogens remain positive for several days after cultures become negative. Thus, if a patient is considered too sick to undergo lumbar puncture on admission, it may be preferable to initiate empirical antibiotic treatment and to reconsider the need for lumbar puncture after 24–48 h, when the patient's condition has stabilized.

A portion of the CSF sample should be examined promptly to determine the number and type of leukocytes present. Bacterial meningitis is usually accompanied by the presence of neutrophils, but about 5 percent of CSF samples subsequently found to be culture-positive contain only a few lymphocytes or no cells at all when first examined. The absence of leukocytes should never be used to justify withholding antibiotic treatment if there is reasonable clinical suspicion of bacterial meningitis. The cell population may consist of a mixture of polymorphs and lymphocytes; this is more likely if there has been a long prodrome or if the patient has been part-treated with antibiotics. A mixture of cells is sometimes seen in viral meningitis. The CSF leukocyte count may be raised in patients who have had a cerebral hemorrhage a few days earlier and in patients who have had recent fits. In these cases, the cells are normally predominantly lymphocytes. Other conditions that give rise to a lymphocytic pleocytosis are listed in Table 1.

The CSF leukocyte concentration falls much more slowly than the concentration of viable bacteria. It is not uncommon for lumbar puncture 1–2 weeks after the onset of bacterial meningitis to show persistence of leukocytes (Chartrand and Cho 1976; Connolly 1979), especially when meningitis has been caused by *H. influenzae* or by a pneumococcus. Persistence of pleocytosis is less likely in meningococcal meningitis.

BIOCHEMICAL ANALYSIS

Estimation of CSF glucose and protein can be helpful. The CSF:blood glucose ratio (normally about 70 percent) is often, though not invariably, reduced in bacterial meningitis, commonly to about 25 percent (Kaplan et al. 1986b), but a normal CSF:blood glucose ratio is common in tuberculous meningitis. The CSF

Table 1 *Conditions causing cerebrospinal fluid lymphocytic pleocytosis*

Infections	Drugs and vaccines	Inflammatory processes	Malignancy
Viral meningitis	Trimethoprim, isoniazid	Postictal, postmyelogram	Meningeal carcinomatosis
Partly treated bacterial meningitis	MMR and polio vaccine	Post-CNS bleed	CNS leukemia and lymphoma
Syphilis	Ibuprofen, NSAIDs	Sarcoidosis, Wegener's granulomatosis	
Parameningeal infection (e.g. abscess, subdural empyema)	Intravenous immunoglobulin	Malignant hypertension, migraine	
Protozoa (e.g. toxoplasmosis)		Kawasaki disease	
Acute and chronic bacterial meningitis		Post-neurosurgery, intrathecal drugs	
Tuberculous meningitis		Multiple sclerosis	
Lyme borreliosis		SLE, Behçet's syndrome	
Fungal meningitis		Benign intracranial hypertension	
Worm infection		Mollaret's meningitis	

CNS, central nervous system; NSAID, nonsteroidal anti-inflammatory drug; SLE, systemic lupus erythemastosus.

protein is often raised, initially reflecting leakage of blood protein into the CSF; later it may reflect local antibody production. CSF lactate concentration may help to differentiate between bacterial and viral meningitis.

Urine reagent strips have been used for the direct examination of CSF (Moosa et al. 1995) to discriminate accurately between viral and bacterial meningitis. This cheap and simple method may have an important role where laboratory facilities are limited or distant.

MICROSCOPY

Direct microscopy of uncentrifuged or centrifuged CSF may reveal the presence of bacteria or fungi and can provide immediate confirmation of the diagnosis. Staining with acridine orange is more sensitive than the Gram stain (Kleinman et al. 1984). The organisms seen on microscopy in antibiotic-treated patients may fail to grow on culture, but the morphology and Gram reaction of the organism, the age of the patient, and the clinical features often permit an educated guess at the identity of the causative organism.

DETECTION OF BACTERIAL ANTIGEN

Tests for bacterial antigen in CSF can provide a quick diagnosis, but they are less sensitive than the Gram stain and do not often alter clinical management (Maxson et al. 1994). Many tests are based on the agglutination of antibody-coated latex particles and work quite well for pneumococci, for meningococci of serogroups A or C, and for group B streptococci. They are less successful for the detection of serogroup B meningococci. The *Limulus* lysate test is a sensitive test for endotoxin from gram-negative organisms but has not found wide acceptance to date.

CULTURE

CSF should be inoculated on to good-quality culture media, always including at least Columbia blood agar and a heated blood agar. Plates should be incubated in five percent CO_2 for a minimum of 48 h. If a ruptured cerebral abscess is suspected, or if meningitis has followed neurosurgery or a history of previous meningeal trauma, a second blood agar plate should be incubated anaerobically for 5–7 days.

The possibility of parameningeal infection, especially subdural empyema and brain abscess, must be considered and pursued actively if CSF shows an inflammatory response, if bacteria are not seen, cultured, or detected by PCR tests, and the patient's condition is not improving. CT scans may sometimes fail to detect intracranial collections of pus. Subdural empyema (or brain abscess) should be suspected if 'meningitis' is diagnosed in a child or young adult in whom there is a recent history of sinusitis or middle ear infection. The importance of not missing these conditions lies in the need for urgent neurosurgical and ear, nose, and throat (ENT) assessment as part of the management protocol. Most cases of subdural empyema are initially misdiagnosed as bacterial meningitis.

POLYMERASE CHAIN REACTION

PCR tests for the detection of meningococcal and pneumococcal DNA in CSF are now used routinely in the UK. Meningococcal PCR is specific and sensitive for the diagnosis of meningococcal meningitis (Borrow et al. 1997) and provides serogroup information in the majority of cases. Amplification of sections of 16S ribosomal RNA, common to most species of pathogenic bacteria, may also prove to be of value (Greisen et al. 1994).

Peripheral blood

BLOOD CULTURE

Blood cultures are positive in only about half of patients with meningococcal disease who have not previously received parenteral antibiotic therapy, and they are almost invariably sterile in those who have. In contrast, in Hib and pneumococcal meningitis the causative organisms are commonly isolated from peripheral blood of untreated patients (British Society for the Study of Infection Research Committee 1995).

MICROSCOPY

When bacteremia is heavy, meningococci and other bacteria may be detected within polymorphs in Giemsa-stained films of peripheral blood (Bush and Bailey 1944) and they can be seen in and grown from tissue fluid obtained from the hemorrhagic skin rash (van Deuren et al. 1993) and from other normally sterile sites such as joints and pericardial fluid.

PCR OF PERIPHERAL BLOOD

PCR tests for the detection of meningococcal DNA (Borrow et al. 1997) are of particular value when the patient has received parenteral antibiotic treatment before hospital admission, an increasingly frequent event. They are now offered routinely in the UK (Kaczmarski et al. 1998), with high sensitivity and specificity (Hackett et al. 2002a). About half of all cases of laboratory-confirmed meningococcal disease in England and Wales are now diagnosed by PCR methodology. This is related to the increasing use of preadmission parenteral antibiotic therapy and to a decline in the use of lumbar puncture, especially in pediatric patients (Wylie et al. 1997). Quantitative meningococcal blood PCR has recently confirmed historical quantitative culture findings, indicating that meningococcal bacterial load at presentation in hospital correlates with disease severity (Hackett et al. 2002b).

Though pneumococcal and Hib meningitis are very frequently accompanied by bacteremia, blood PCR tests for these bacteria are not used widely. Blood PCR tests for pneumococci are only moderately sensitive, and the specificity is low in children (better in adults), either because they fail to differentiate between carriage and invasive infection or, more likely, 'occult' bacteremia (or spillover of bacteria from the nasopharynx) is a frequent occurrence in colonized infants and children.

Serology

Serological tests for meningococcal disease were long hampered by the failure of serogroup B capsular polysaccharide to provoke a good immune response. Second-generation serological tests now available in the UK can reliably detect the presence of acute-phase (IgM) meningococcal antibodies in a single serum specimen obtained after the first week of the illness; alternatively, a rising titer of antibody to meningococcal outer-membrane proteins may be sought (Jones and Kaczmarski 1994).

Serology can be used to confirm invasive Hib infection but antibody responses in pneumococcal infection are highly unreliable because they fail to differentiate between carriage and invasive illness.

Nasopharyngeal swabs

Since the main bacterial meningitis pathogens are nasopharyngeal commensals, their isolation from the nasopharynx in cases of clinical meningitis does not provide evidence of causation. However, when lumbar puncture is not undertaken and blood cultures are negative, a throat swab may give the only chance of obtaining an isolate. Meningococci are rarely recovered from healthy infants and the isolation of a capsulate meningococcus of serogroup B or C from the posterior pharynx of a young child with symptoms of meningitis with or without a hemorrhagic rash is very strong evidence of a meningococcal etiology. Similarly, the isolation of Hib from a child with meningitis aged 12 months or less is unlikely to be coincidental. However, isolation of a pneumococcus from the nasopharynx of a child or adult is sufficiently common that it does not assist in management.

Swabs of the posterior pharynx are ideally taken through the mouth (Olcén et al. 1979). Patients with clinical meningitis are often too ill to cooperate with peroral swabbing, but pernasal swabs are simple to obtain, though an assistant is required to steady the patient's head. A single negative nasopharyngeal swab is an insensitive predictor of freedom from carriage of any specific bacterial meningitis pathogen, and decisions on the prophylaxis of contacts of meningococcal or Hib disease should never be based on the results of nasopharyngeal swabbing of the contacts.

MENINGOCOCCAL DISEASE

Historical aspects

Vieusseux (1805) described an outbreak of meningococcal disease with 33 deaths in the small community of Eaux Vives, near Lake Geneva in Switzerland, in the spring of 1805. Before this, meningococcal disease may have been confused with other spotted fevers, including typhus, which also sometimes occurred in clusters and outbreaks, especially in the military, and was often characterized by a hemorrhagic skin rash. It seems most likely that meningococcal disease has afflicted man for centuries.

August Hirsch (1886) documented many outbreaks of infectious diseases including cerebrospinal fever in Europe and the New World up to 1882. The Italian pathologists Marchiafava and Celli (1884) are credited with the first description of intracellular oval micrococci in a sample of CSF. Three years later Weichselbaum, in Vienna, reported the isolation of an organism he described as *Diplococcus intracellularis meningitidis* from six of eight cases of primary sporadic community-acquired meningitis (Weichselbaum 1887). A period of confusion followed when Jaeger isolated a gram-positive chain-forming coccus from meningitis cases in an outbreak in Stuttgart. Subsequent reports showed that Weichselbaum was correct: Jaeger's gram-positive organism was probably a contaminant.

Eight years later came the first account of lumbar puncture in a living patient (Quincke 1893), and in 1896 meningococci were isolated for the first time from the CSF of patients with meningitis (Heubner 1896). In the same year, meningococci were also isolated from human throat cultures (Kiefer 1896), offering an explanation for the spread of the bacteria in human populations.

Before World War I, German and American bacteriologists were developing serum therapy for meningococcal meningitis in an effort to reduce its extremely high mortality (Kolle and Wasserman 1906; Flexner and Jobling 1908). They were able to reduce mortality from about 80 to 25 percent by repeated intrathecal instillation of immune horse serum (Flexner and Jobling 1908). Not surprisingly, a number of successfully treated patients developed 'serum disease' (serum sickness), with fever and arthritis, and a few developed secondary bacterial meningitis.

In Britain, nationwide notification of a range of infectious diseases including cerebrospinal fever was introduced in 1912. Two years later, during the first winter of World War I, there were several outbreaks of cerebrospinal fever amongst military recruits. Glover (1920) carried out a detailed investigation at the Guards Depot, Caterham, in south London. His report is a masterpiece of early meningococcal epidemiology; he concluded that the disease flared up at times of extreme overcrowding

and was preceded by very high nasopharyngeal carriage rates. Effective interventions, including increasing the amount of sleeping accommodation and the space between beds, fixing open windows in huts, and shortening of parades, brought the outbreaks to a halt, even during the 1918–19 winter in which there was a major influenza epidemic. Later, Dudley and Brennan (1934) and others documented very high nasopharyngeal carriage rates without the occurrence of cases of meningococcal disease. All the major combatant countries in World War I experienced clusters of cases and outbreaks of meningococcal disease in recruit camps, but there was little disease in seasoned troops (Rolleston 1919). At the end of the war, French microbiologists published a serogrouping scheme, which forms the basis for the current classification system (Nicolle et al. 1918).

In the 1930s, Rake and colleagues showed that freshly isolated meningococci were 'smooth' (capsulate), that they produced a polysaccharide capsule and that such strains produced more potent antisera when used to immunize horses (Rake 1931; Rake and Scherp 1933). Rake also carried out studies on the duration of nasopharyngeal meningococcal carriage and showed that, though very variable, carriage could persist for years.

Rake's work, which was leading towards the development of vaccines, was halted by the discovery of sulfonamides. After their first use in the treatment of human meningococcal infections (Schwentker 1937), sulfonamides were used to treat very large numbers of cases of meningococcal disease at the beginning of World War II and, subsequently, also for chemoprophylaxis. In Britain in 1941, there were 11 000 notified cases and more than 2 000 cases in each subsequent year up to 1945 (Figure 2).

Germany, France, and the USA also experienced outbreaks of unprecedented size, in each case shortly after becoming a combatant country. These epidemics occurred in association with mobilization (in 1940–41 in the UK, France, and Germany, and in 1942–43 in the USA) and usually began among recruits in training, later spilling over into civilian populations. At the same time, most noncombatant countries, such as Sweden, did not experience any great change in the incidence of meningococcal disease.

Sulfonamides transformed the treatment of meningococcal disease – mortality rates fell to about 10–20 percent. When penicillin became available later in the war it gradually superseded sulfonamides for treatment of invasive disease, but sulfonamides continued to be used for the treatment of carriers.

Epidemiology

Meningococcal disease remains a worldwide problem, occurring sporadically as clusters of cases and as epidemics. Annual rates of disease in many western countries and in the North American continent are about one to two per 100 000 of the total population, though there are wide fluctuations from year to year and from country to country. Even within countries, the disease rate can fluctuate remarkably, with clustering of cases in small communities or regions, giving high attack rates (5–25 per 100 000) for months or years. Norway experienced high rates of disease, mainly due to strains of serogroup B (ET-5 clone), for almost 20 years from the 1970s to the 1990s (Lystad and Aasen 1991), whereas the disease incidence in Sweden remained low throughout the same period. At the start of a period of increased disease incidence, the average age of cases rises (Peltola et al. 1982) and the severity of disease is greater. These phenomena may reflect the accumulation of susceptible people in the population. New Zealand has experienced hyperendemic serogroup B

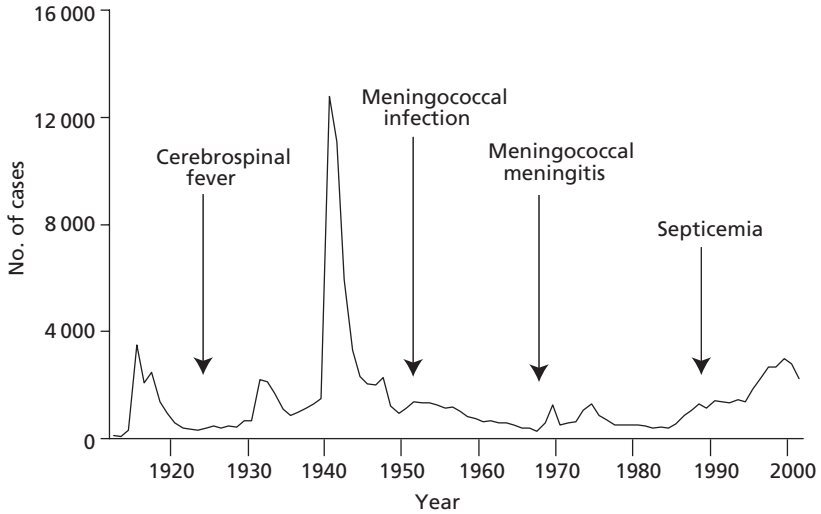

Figure 2 *Notifications of meningococcal disease, England and Wales 1912–2001.*

meningococcal disease since the early 1990s, with particularly high attack rates amongst the Pacific Islander and Maori populations (Martin et al. 1998).

THE 'MENINGITIS BELT'

The pattern of disease is quite different in some tropical countries, with large epidemics of serogroup A disease occurring at irregular intervals, separated by periods of much lower disease activity (Peltola 1983; Moore 1992). Lapeysonnie (1963) drew attention to an area of Africa south of the Sahara and extending almost from coast to coast, where epidemics of meningococcal disease occur every 5–10 years – the 'meningitis belt' (Figure 3). Epidemic waves may last 2 or 3 years.

The boundaries of the meningitis belt are probably defined by climatic factors; continuous high absolute humidity may reduce meningococcal transmission (Cheesbrough et al. 1995). This leads to the situation in sub-Saharan Africa, where countries such as Ghana and Nigeria may experience epidemics of meningococcal disease in their northern regions but have low attack rates in their southern coastal areas.

The disease is highly seasonal in the meningitis belt, with an upsurge during the period of dry, dusty winds ('harmattan'), with abrupt cessation of the epidemic with the start of the rainy season. The numbers of cases are staggering by developed country standards – attack rates of 500 per 100 000 or more have been recorded. The highest attack rate is in the age group 5–15 years; the sexes are affected equally. Multilocus electrophoretic typing (Caugant et al. 1987) and multilocus sequence typing (Maiden et al. 1998), which permit the identification of meningococcal clones, demonstrate that these epidemics are usually due to the spread of new clones, almost always of serogroup A (Olyhoek et al. 1987; Achtman 1990, 1995).

EPIDEMIOLOGY IN TEMPERATE CLIMATES

In temperate and colder climates, the disease is strongly seasonal, with peak rates in the winter months. In Britain, disease rates are highest in December and January, falling to a low point in the autumn months. In western countries, the age-specific incidence shows two peaks, with the first, and larger, in infants and young children. A second smaller, but important, peak occurs in late teenage. There is no obvious relationship between the age-specific prevalence of carriage and the incidence of disease (Figure 4). In most western countries, affected males outnumber females by up to 1.5:1.

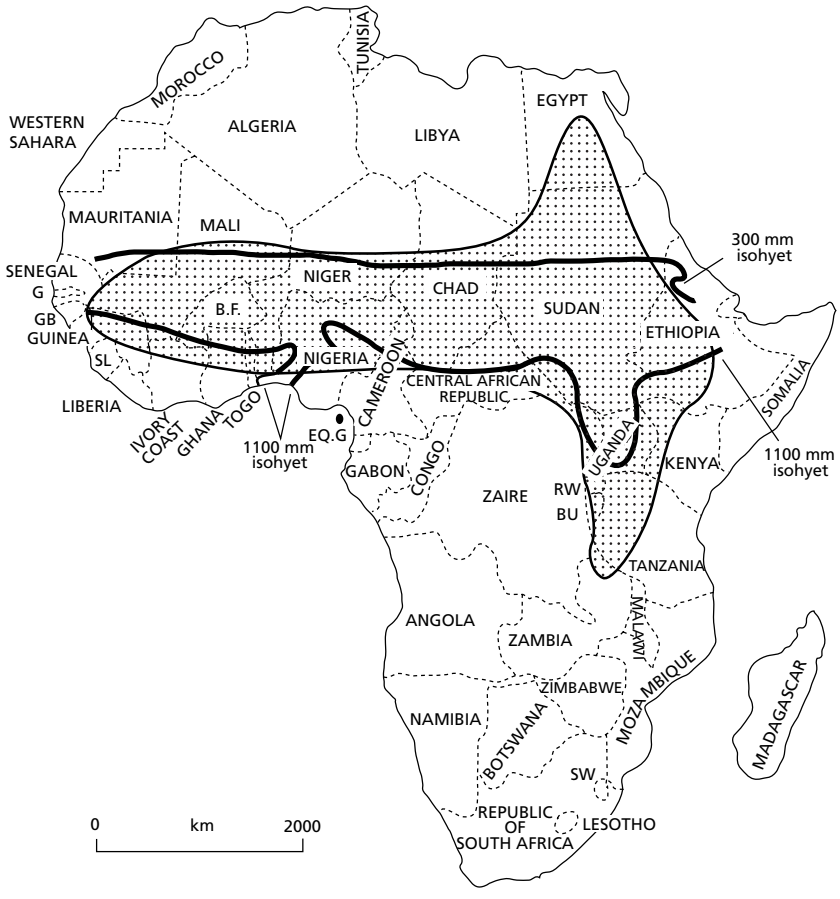

Figure 3 *Africa: the 'Meningitis Belt' (redrawn from Cheesbrough et al. 1995 with permission).*

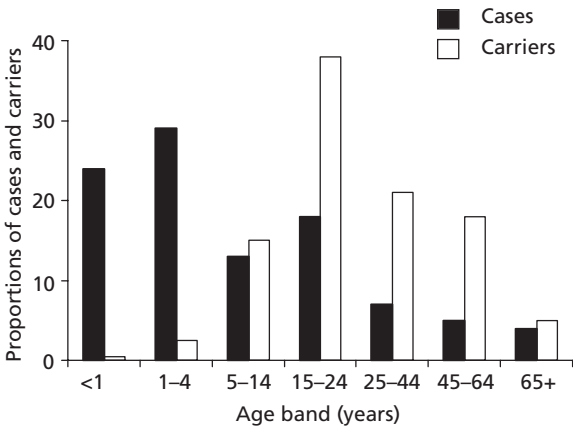

Figure 4 *Proportions of meningococcal cases and carriers within age groups. (Carriage data from Cartwright et al. 1987, with permission; age incidence from Jones and Mallard 1993, with permission.)*

In the UK, prior to the introduction of conjugated meningococcal serogroup C vaccines in 1999, about 70 percent of invasive disease was caused by serogroup B meningococci, a further 25 percent by serogroup C strains, and the remainder by a mixture of other serogroups, including W-135, Y, and X (Jones and Kaczmarski 1994). The large epidemics that occurred during World War I and World War II were caused by strains of serogroup A, with a major change in the epidemiology occurring in the 1950s to the currently observed pattern. During the late 1990s in the UK, the proportion of cases attributable to serogroup C strains has been as high as 40 percent. This was accompanied by a higher incidence of cases in older children and adults and an increase in the number of outbreaks in schools and universities. The introduction into the national childhood immunization schedule in November 1999 of highly effective conjugated serogroup C vaccines has dramatically reduced serogroup C disease in the UK (see below). It has not been accompanied by replacement of serogroup C disease by strains of other serogroups, e.g. serogroup B, either amongst disease-causing strains or amongst carried meningococci (Maiden et al. 2002).

In the UK, the USA, and a number of European countries, there was a notable upsurge in meningococcal disease caused by strains of W-135 amongst Muslim pilgrims making the Haj pilgrimage to Mecca and Medina in 2000 (Taha et al. 2000) and 2001. A requirement by the Saudi Arabian health authorities later in 2001 that all pilgrims should receive quadrivalent A, C, Y, W-135 vaccine as a condition of entry to the country brought these outbreaks of disease to a close. The clone causing this upsurge of W-135 disease was the same as that responsible for most serogroup C meningococcal disease in the UK over the preceding few years (ET-37). This clone is highly virulent and case-fatality rates were high.

Carriage

This subject has been dealt with in two in-depth reviews (Broome 1986; Cartwright 1995). The human nasopharynx is the natural habitat of the meningococcus. Meningococci are not carried by animals; nor are they recovered from the environment. Humans may be selectively colonized because meningococci are only able to acquire iron, an essential nutrient (van Putten 1990), from human (and primate) transferrin and lactoferrin (Schryvers and Gonzalez 1990). Fimbriae facilitate binding to human epithelial cells, but capsulation, essential for invasion, reduces adherence. Colonization by a single strain may last for months or even years. Capsule expression may be downregulated during prolonged carriage.

AGE-SPECIFIC INCIDENCE OF CARRIAGE

Carriage rates are low in infants and young children but rise with age to peak in late teenage and early adult life. They then decline slowly over the next 20–30 years; carriage is rare after the age of 65 years (Greenfield et al. 1971; Cartwright et al. 1987; Caugant et al. 1994). Most nasopharyngeal meningococci have very low invasive potential. Many express little or no capsular polysaccharide and are nongroupable or belong to serogroups of low virulence such as X, Y, or W-135. Exposure to such strains probably boosts levels of antibody against noncapsular surface antigens.

FACTORS AFFECTING CARRIAGE RATES

Throat-swabbing is an insensitive procedure and swabs from individuals and groups underestimate carriage frequency. Swabbing the posterior pharyngeal wall is much more reliable for the detection of meningococcal carriage than swabbing the tonsils or sampling the front of the mouth (J.M. Stuart, unpublished), but a single negative throat swab, even if collected by an experienced sampler, cannot be relied upon as proof of freedom from colonization. Somewhat surprisingly, carriage appears to be unaffected by season (Blakebrough et al. 1982; de Wals et al. 1983) or by intercurrent viral infection. Vaccination with purified capsular polysaccharides also appears to have little effect, but conjugated serogroup C vaccines have reduced dramatically the prevalence of carriage of homologous meningococcal strains (Maiden et al. 2002).

Smoking has a strong dose-related effect on carriage (Stuart et al. 1989), but contact with a case of meningococcal disease is the most important risk factor for carriage. Rates of carriage are high in family members and close contacts of cases of meningococcal disease (Greenfield and Feldman 1967; Munford et al. 1974; Kristiansen et al. 1998). Most (but not all) such isolates are indistinguishable from the index case strain (Olcén et al. 1981). Carriage rates rise rapidly when teenagers

and young adults are brought into close contact and close social interaction, such as that facilitated by entry into a military recruit camp (Riordan et al. 1998) or commencing study at university (Neal et al. 2000), explaining the high rates of disease seen in these groups. For students, high carriage rates and high disease rates are most marked in the freshman (first) year.

Immunity

The best serological correlate of protection from meningococcal disease is the presence of bactericidal antibodies (Goldschneider et al. 1969a) (Figure 5). Opsonizing antibodies are also important (Halstensen et al. 1989). For serogroup A and C meningococci, most bactericidal antibody is IgG directed against the capsular polysaccharide and is capable of causing bacterial lysis through the activation of complement (Gotschlich et al. 1969a). Serogroup B capsular polysaccharide is a very weak antigen for humans, probably because it shares epitopes with host cell antigens (Finne et al. 1983; Azmi et al. 1995). Antibodies present after serogroup B meningococcal disease are directed against a variety of surface-expressed antigens, including outer-membrane proteins and lipopolysaccharide (Kasper et al. 1973; Griffiss et al. 1984).

THE ROLE OF *NEISSERIA LACTAMICA*

Bactericidal antibodies are acquired progressively during childhood (Goldschneider et al. 1969a), beginning at a time when exposure to meningococci is slight. Thus, protection is probably acquired first through exposure to other bacteria that express cross-reacting surface antigens (Glode et al. 1977; Guirguis et al. 1985; Devi et al. 1991).

The carriage rate of *Neisseria lactamica* is high when bactericidal meningococcal antibodies are being acquired. Colonization with *N. lactamica*, a noncapsulate species, generates antibody that is bactericidal against a range of serogroups and serotypes of meningococci (Gold et al. 1978), indicating the presence of cross-protective subcapsular antigenic determinants. Later in life, exposure to avirulent meningococci induces antibodies against a wide range of meningococcal serogroups (Reller et al. 1973), providing further confirmation that some bactericidal antibody is directed against noncapsular antigens. A number of oral and enteric bacteria also express cross-reactive antigens and probably play a part in generating and maintaining immunity.

BLOCKING IGA ANTIBODIES

Complement-dependent immune lysis is not initiated by IgA. However, secretory or circulating IgA antibodies may block meningococcal surface antigens that would otherwise be accessible to IgG or IgM antibodies that activate complement. Blocking IgA antibodies generated in response to cross-reacting enteric bacteria may be important in some cases of meningococcal disease in older children and adults (Griffiss 1995). The timing of exposure to the meningococcus and the cross-reacting enteric bacterium may be critical (Kilian and Reinholdt 1987; Kilian et al. 1988).

HOST SUSCEPTIBILITY

Various congenital or acquired immune deficiency syndromes are associated with an increased risk of meningococcal disease (Figueroa and Densen 1991). Deficiency of any of the terminal complement components (C5 to C9) is associated with an increased risk of meningococcal disease, especially of serotypes not normally regarded as invasive, including X, Y, and W-135 (Fijen et al. 1989). The risk of second and subsequent attacks is also increased but disease tends to be milder (Ross and Densen 1984). Half the individuals with the very rare deficiency of properdin (factor P) develop meningococcal disease, but this tends to occur in older children or adults and is often overwhelming, with high fatality rates (Densen et al. 1987). There are at least three genetic mechanisms leading to properdin deficiency; all three identified to date are inherited in an X-linked manner (Linton and Morgan 1999).

Recent evidence suggests that mannose-binding lectin, part of a phylogenetically older innate immune system,

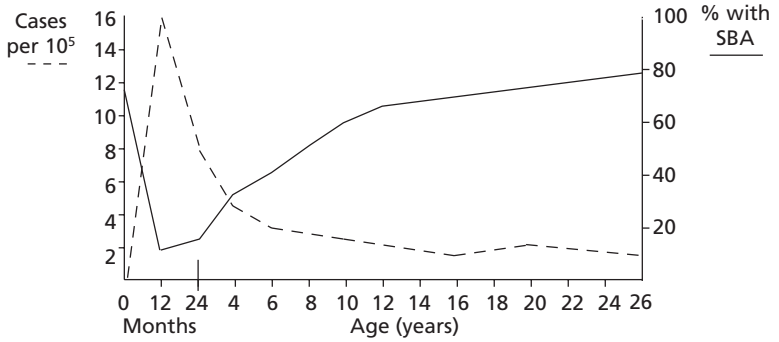

Figure 5 *Meningococcal disease: relationship to bactericidal antibodies (after Goldschneider et al. 1969a, with permission).*

plays an important role in early defense from meningococcal (and other invasive bacterial) infections (Summerfield et al. 1997), and mutations in the mannose-binding lectin gene may be associated with an increased susceptibility to meningococcal infection. There is also evidence that particular patterns of inherited cytokine profile may be associated with a higher risk of a fatal outcome in meningococcal disease (Westendorp et al. 1997). More recently, polymorphisms of genes encoding plasminogen activator inhibitor 1 and IL-1β have been shown to be associated with the development of septic shock or with increased mortality in meningococcal disease (Westendorp et al. 1999; Read et al. 2000), and FcγRIIa (CD32) polymorphisms appear to be associated with susceptibility to, and severity of, meningococcal disease (Bredius et al. 1994; Platonov et al. 1998).

SUSCEPTIBILITY AT DIFFERENT AGES

Meningococcal infection is infrequent in the first 2 months of life, indicating the likely key role of passively transferred maternal antibodies in initial protection. Subsequently, meningococcal disease in infants and young children probably results from exposure of an immunologically virgin child to a virulent meningococcus. Carriage studies suggest that exposure to virulent meningococci is probably uncommon in infancy. This seems less likely in teenagers and young adults in whom there is also a peak of infection (see Figure 4), but at a time when meningococcal carriage is most frequent. Most, if not all, individuals aged 10 years or more will probably have encountered *N. lactamica*, poorly capsulate meningococci, and/or other immunizing bacteria on numerous occasions. Therefore, meningococcal disease in this age group may result from inherited increased susceptibility, a high level of exposure to meningococci, subversion of pre-existing defense mechanisms by environmental factors such as antecedent or intercurrent viral infection, or a combination of these factors.

Meningitis and septicemia

Meningococcal infection most commonly presents as meningitis (75 percent) or septicemia (20 percent), though the two syndromes show considerable overlap; clinical differentiation may be difficult or impossible, and UK clinicians vary in their practice as to what disease they choose to notify; recently, proportionately more cases have been notified as septicemic (Figure 6).

A few patients have other pyogenic infections such as primary septic arthritis, conjunctivitis, and pericarditis. Primary meningococcal pneumonia is usually caused by strains of serogroup Y. Increasing numbers of cases have been reported from the USA in recent years, and this condition may be underdiagnosed in the UK.

The outlook in meningococcal meningitis is very good. Mortality in the UK is less than 5 percent, and the incidence of long-term neurological morbidity, mainly deafness, is low (3–5 percent), though a small percentage of survivors suffer severe or even catastrophic brain damage. Most meningococcal meningitis occurs in infants and young children in whom the symptoms and signs are similar to those of other types of bacterial meningitis occurring at the same age. A common, though not invariable, feature of meningococcal meningitis is the presence of petechiae or purpura in the skin. Though an ecchymotic skin rash may also occur occasionally in Hib or pneumococcal meningitis (and in a wide range of noninfectious conditions), it is seen in more than 50 percent of cases of meningococcal meningitis and in all cases of meningococcal septicemia. The pathology of the skin lesions resembles a series of localized Shwartzman reactions (DeVoe 1982). Nondescript, macular, flat or raised nonvasculitic, evanescent skin rashes are very common in the early stages of development of meningococcal infection in children (Marzouk et al. 1991). They may be mistaken for the rash of viral infection and may cause delay in diagnosis. Such rashes

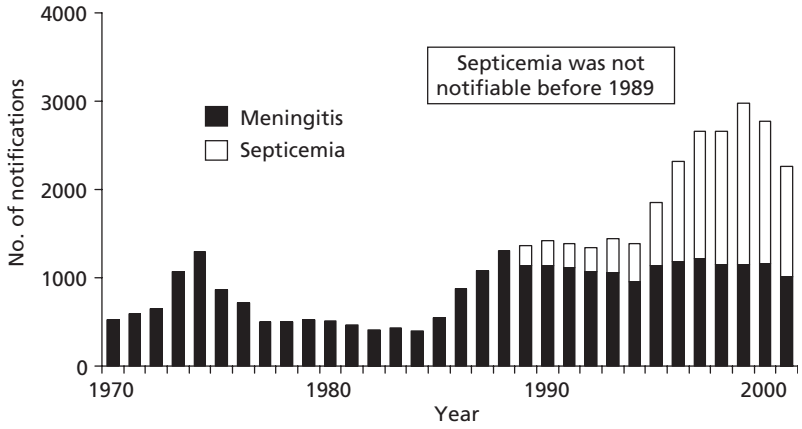

Figure 6 *Meningococcal disease, England and Wales: annual numbers of notifications, 1970–2001*

disappear with the onset of the more characteristic vasculitic rash.

Meningococcal meningitis in older patients usually presents with symptoms of malaise, muscular aches and pains, diarrhea together with vomiting, fever, and headache, progressing if unrecognized to confusion, coma, shock, and circulatory collapse. In the later stages, an ecchymotic skin rash is almost inevitable.

Septicemia in children or adults is a far more serious condition, with a mortality greater than 20–25 percent. It can occur with or without evidence of meningitis. Fever, shock, and an ecchymotic skin rash are the hallmarks of this condition. Onset is frequently abrupt, over a few hours. Multisystem failure is common. In addition to antibiotics, oxygen, aggressive fluid replacement, correction of electrolyte imbalances, inotropes, mechanical ventilation, control of disseminated intravascular coagulation, and hemodialysis may all be required for considerable periods. Survivors of severe septicemia may need amputations of necrotic fingers, toes, or sometimes limbs; a few suffer severe brain damage, probably associated with prolonged periods of hypotension and hypoxia.

Management

ANTIBIOTIC TREATMENT

Benzylpenicillin has traditionally been regarded as the drug of choice in meningococcal disease. The England Chief Medical Officer recommends that general practitioners and casualty doctors should administer a dose of benzylpenicillin to any patient with suspected meningococcal disease, without awaiting the results of laboratory investigations. This course of action may halve mortality in the more seriously ill and is strongly endorsed, though it makes confirmation of the diagnosis somewhat more difficult (Cartwright et al. 1992) (Figure 7). Fortunately, the availability of molecular diagnostic tests on blood and CSF have largely obviated this problem. The combination of fever and a vasculitic (nonblanching) skin rash must be taken to indicate the possibility of meningococcal disease until an alternative diagnosis is established. This combination of symptoms constitutes a medical emergency. As well as administering benzylpenicillin, general practitioners are urged to arrange immediate ('blue-light') transfer of the patient to hospital.

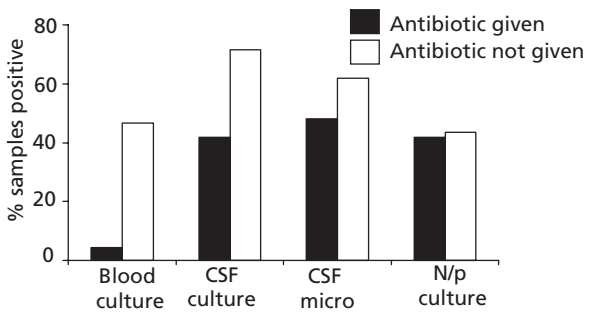

Figure 7 *Effect of parenteral antibiotics on laboratory investigations in meningococcal disease (from Cartwright et al. 1992, with permission).*

Since the etiology will probably not be known for certain at the start of inpatient treatment, it is wise to use a broad-spectrum antibiotic for the first 24–48 h, especially in young children. Cefotaxime, ceftriaxone, or, if cost is a factor, chloramphenicol are suitable alternatives that give high rates of cure; these agents can also be used in patients who are allergic to penicillin. Cefuroxime is inferior. Treatment may be switched to benzylpenicillin when a meningococcal etiology has been confirmed. Wall has argued for the use of cefotaxime or ceftriaxone as agents of first choice for treatment of meningococcal meningitis throughout on grounds of high activity and high penetration into the subarachnoid space (Wall 2001). In view of the very high success rates achieved with benzylpenicillin in this condition, prospective randomized trials would be very difficult or impossible.

'Penicillin-resistant' meningococci

So-called 'penicillin-resistant' meningococci have been reported in a number of countries and regions, including Spain (Sáez-Nieto et al. 1992), South Africa, the UK, and the North American continent. These strains are better described as showing reduced sensitivity to penicillin, and it is likely that such reduced sensitivity results from acquisition of genetic material from related neisserial species including *Neisseria flavescens*, an oropharyngeal commensal, leading to production of an altered penicillin-binding protein 2 (Spratt et al. 1989). Illness caused by these strains responds almost invariably to treatment with adequate doses of benzylpenicillin.

Production of β-lactamase by meningococci isolated from invasive infections has been reported from South Africa and Spain (Botha 1988; Fontanals et al. 1989). Neither strain has survived for detailed investigation. In view of the known transformability of meningococci, it is more than a little surprising (albeit very welcome) that β-lactamase-producing meningococci have not been encountered more often.

Duration of antibiotic treatment

Antibiotic treatment for 7 days usually suffices for children with mild illness (McCracken et al. 1987; O'Neill 1993). Longer periods of treatment, of at least 10 days, are often used in more seriously affected patients, including those with septicemia, even though all meningococci are likely to have been killed soon after the commencement of treatment. Very occasionally, meningococci may survive within the subarachnoid

space in a loculated space after a short period of antibiotic treatment, subsequently to re-emerge and to cause relapse. Normally, they are killed and cleared rapidly from the subarachnoid space (Feldman 1977; Kanegaye et al. 2001).

STEROIDS AND IMMUNOMODULATORS

The role of steroids in meningococcal disease remains controversial. A meta-analysis of trials undertaken in the 1990s showed a reduction in the incidence of neurological sequelae, mainly deafness, in patients with bacterial meningitis when dexamethasone was given before or with the first dose of antibiotics (Feigin et al. 1992; Schaad et al. 1993; Jafari and McCracken 1994). Most patients had Hib meningitis. Since the pathology of neurological damage is probably similar for the three main bacterial pathogens, it seems logical to endorse this addition to the treatment of meningococcal and pneumococcal meningitis. Steroids are ineffective in bacterial meningitis if given more than about an hour after the first parenteral dose of antibiotic. A 2-day course is probably as effective as treatment for 4 days (Syrogiannopoulos et al. 1994). After 48 h the cytokine inflammatory cascade in the CSF should have stabilized.

There is no evidence to support the use of dexamethasone in meningococcal septicemia (Nadel et al. 1995). Various novel therapies for severe meningococcal disease are under consideration or evaluation, including antiendotoxins, anticytokine response agents, leukocyte activation antagonists, cardiovascular support agents, and many others (Nadel et al. 1995). Some encouraging results have been achieved in small uncontrolled studies (Giroir et al. 1997; Goldman et al. 1997; Smith et al. 1997).

Recent evidence indicates that case-fatality rates in meningococcal infection have fallen significantly in centers of excellence (Thorburn et al. 2001; Booy et al. 2001). These analyses indicate that this is almost certainly due to improved clinical management, since the trend to lower mortality was based on children with comparable disease severity scores. The marked trend to lower case-fatality rates that has been observed nationally across the UK could reflect relatively more efficient ascertainment of surviving cases than fatal cases but is also likely to include a number of other factors, including earlier recognition of possible meningococcal infection by parents of young children, the greater use of pre-admission parenteral penicillin, and improved management in hospital. The UK national case fatality rate is now below 7 percent and maintaining a falling trend.

SECONDARY CASES AND CLUSTERS

Close contacts of cases of meningococcal disease run an increased risk of developing disease in the days and weeks after exposure to an index case, especially a first-degree relative living in the same household. The increased risk may be due to exposure to a known pathogenic strain, an inherited susceptibility to meningococcal infection, transient exposure to a common environmental factor (e.g. influenza virus) (Harrison et al. 1991), or a combination of these. An attempt has been made to estimate the proportion of risk attributable to host factors by calculating the sibling familial risk ratio (Haramboulos et al. 2003); these authors estimated that host genetic factors contributed approximately one third of the risk.

The nasopharyngeal carriage rate of meningococci is high in close family contacts of cases (Kristiansen et al. 1998). Rifampicin, ciprofloxacin, and ceftriaxone are all more than 90 percent successful in eliminating nasopharyngeal colonization in contacts (Cuevas and Hart 1993). They also reduce the incidence of secondary cases of disease in the 30–60 days after the illness of the index case. Though there have been no large prospective trials to establish the benefit of chemoprophylaxis, and though there is no evidence to show that the risk of secondary disease is reduced in the longer term, it is accepted policy to offer chemoprophylaxis to defined close contacts (Meningococcal Infections Working Group 1989). If the index case strain is of serogroup A or C, close contacts should also be offered A + C vaccine. Regardless of the causative organism, all contacts should be informed about their increased risk of meningococcal disease, which may persist for many months, especially when chemoprophylaxis has been given.

Clusters of cases sometimes occur in playgroups, schools, universities, military establishments, and other closed and semiclosed communities. Serogroup C strains are more commonly isolated in such outbreaks. Consideration should be given to the value of chemoprophylaxis, with or without vaccination, but each situation must be judged on its merits. The level of public alarm is often at variance with the actual risk (Hastings et al. 1997; Stuart et al. 1997). Cases of meningococcal disease occur occasionally in laboratory workers who have been handling the organism. Safety cabinets must always be used when handling liquid suspensions of virulent meningococci (Boutet et al. 2001).

Multilocus sequence typing (MLST) (Maiden et al. 1998) and other molecular characterization methods will play an increasingly important role in elucidating meningococcal microepidemiology and facilitating rational management of clusters and community outbreaks. MLST can also be applied to other genetically diverse bacterial species such as pneumococci, *Haemophilus influenzae*, etc.

Vaccines

The first vaccines for the prevention of meningococcal disease were developed in 1912 (Sophian and Black

1912). Uncontrolled field trials of a whole-cell meningococcal vaccine took place in England during World War I (Greenwood 1916). In the 1930s, Scherp and Rake (1935) identified capsular material from a meningococcus as a polysaccharide, but work on vaccine development, driven by outbreaks of disease amongst military recruits, waned when sulfonamides and then penicillin became available. With the emergence of sulfonamide resistance in the 1960s, interest in prevention by vaccination was reawakened, stimulated by the inability to control clusters of cases in recruit camps by sulfonamide prophylaxis. In a series of classical papers, Gotschlich, Goldschneider, and their colleagues at the Walter Reed Army Institute of Research, Washington, USA, demonstrated the fundamental importance of bactericidal antibodies in determining protection from invasive meningococcal disease. They went on to develop the first serogroup C polysaccharide vaccine to be properly evaluated in humans (Goldschneider et al. 1969a, b; Gotschlich et al. 1969a, b; Artenstein et al. 1970). Soon after this, a large clinical trial of a serogroup A polysaccharide vaccine was reported from Finland (Peltola et al. 1977), and further serogroup A vaccine studies in Africa followed.

SEROGROUP A AND C VACCINES

Vaccines containing serogroup A and C polysaccharides have been used quite widely in the UK, and quadrivalent A, C, Y, and W-135 vaccine is also available. Their use has declined with the availability of conjugated serogroup C vaccines (see below). Purified polysaccharide (i.e. nonconjugated) vaccines are not immunogenic in infants and give only short-term (3–4 years) protection to older children and adults. They are not suitable for universal use and are employed in a more limited set of circumstances (see Table 2).

A conjugated serogroup A and C vaccine has undergone preliminary evaluation in the Gambia (Twumasi et al. 1995). In the UK, conjugated serogroup C vaccines were evaluated in the latter half of the 1990s, were found to be safe and effective, and were then offered to all infants and older children commencing in November 1999 in the face of a high incidence of serogroup C disease (Miller et al. 2002). Their impact has been immediate and dramatic in the targeted age groups, with a reduction in serogroup C disease incidence now exceeding 80 percent (Figure 8). These conjugated vaccines also reduce the carriage of serogroup C meningococci (Maiden et al. 2002), and an impact on those older people who were not initially offered the vaccine is now becoming apparent, driven by reduced exposure, i.e. herd immunity. The exploitation of herd immunity as a deliberate strategy in the vaccine control of meningococcal disease has been advocated by Stephens (1999).

Table 2 *Uses of meningococcal serogroup A + C nonconjugated vaccine*

Uses
Protection of contacts
Protection of travelers to endemic areas
Control of epidemics
Outbreak control in defined communities
Outbreak control in open communities

Prior to the introduction of conjugated serogroup C vaccines in the UK, most serogroup C disease was caused by a single clone (ET-37). Since it was known that naturally occurring strains of this clone were capable of expressing a serogroup B capsule (as opposed to the much commoner expression of a serogroup C capsule), fears were expressed that though serogroup C disease might be reduced, this could be followed by an expansion of the population of ET-37 strains expressing the serogroup B capsule, with a consequent increase in the incidence of serogroup B disease. Despite very careful ongoing monitoring of both invasive and carried meningococcal strains, to date there is no evidence either of an increase in serogroup B disease overall or of any expansion in the numbers of cases of ET-37 serogroup B disease.

Conjugated meningococcal serogroup A vaccines are now being developed and subjected to clinical trials in the sub-Saharan meningitis belt in a program enjoying substantial funding from a US charitable foundation. The ultimate aim of the program is to offer serogroup A (or possibly A + C) conjugated vaccines to at-risk individuals across the whole meningitis belt, with a view to controlling epidemic meningococcal disease in this region.

Conjugated A, C, Y, and W-135 vaccines are also being developed and could have applications in the USA, where serogroup Y strains contribute significantly to the total burden of meningococcal disease, and also in travelers.

SEROGROUP B VACCINES

Serogroup B meningococcal polysaccharide is a weak antigen in humans and prospects for effective serogroup B vaccines are more distant. Occasionally, serogroup B disease can become hyperendemic, and a single strain variant can become responsible for the great majority of cases. In such circumstances it is possible to develop outer-membrane vesicle vaccines against the causative strain of meningococcus. Such vaccines have been developed in Norway (Bjune et al. 1991) and in Cuba (de Moraes et al. 1992); however, neither was effective in infants and there is some evidence that the duration of protection may be limited. In most countries (including the UK), serogroup B disease is caused by a heterogeneous range of serogroup B strains, and the approach of using a single serogroup B variant as the basis for a vaccine is inapplicable.

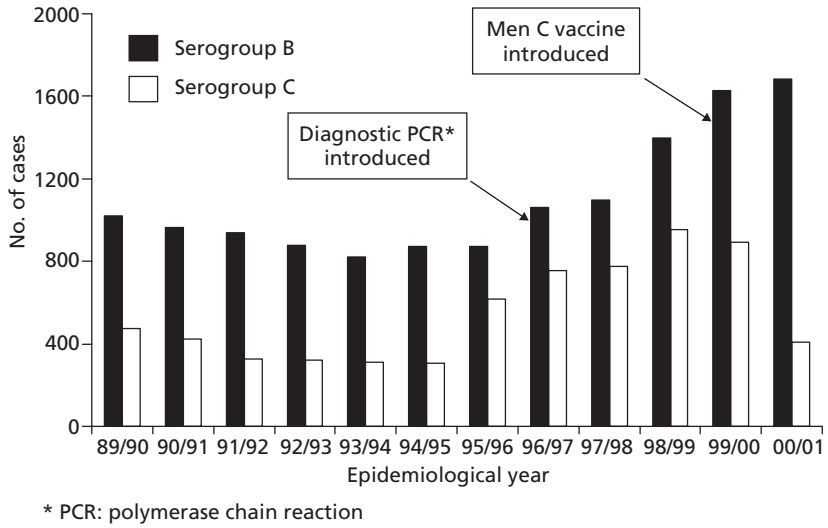

Figure 8 *Laboratory-confirmed cases of meningococcal disease by epidemiological year (July–June), England and Wales, 1989–90 to 2000–01.*

Since bactericidal antibody to serogroup B meningococci is directed against surface components other than the capsular polysaccharide, much effort is being invested in the search for stable, surface-expressed serogroup B antigens or epitopes that will evoke the development of human bactericidal antibodies (Poolman et al. 1995). However, meningococci are very well adapted human colonizers and many outer-membrane proteins have hypervariable regions, presumably to evade the host immune response. A further problem hampering development of serogroup B vaccines is the lack of correlation between the immune responses to candidate antigens in laboratory animals and in man.

Among the antigens currently under investigation are the class 1 outer-membrane protein (van der Ley and Poolman 1992; van der Ley et al. 1993) and iron-binding and iron-regulated proteins (Frasch 1995). Vaccines based on conjugated, chemically modified B polysaccharide are also being explored (Fusco et al. 1997). The recent publication of the entire genetic sequence of a well-characterized serogroup B meningococcus, MC58 (Tettelin et al. 2000) has facilitated the search for genes encoding surface-expressed, well-conserved antigens and may result in the identification of a number of novel targets relevant for vaccine development (Pizza et al. 2000). Progress in the development of serogroup B (and other meningococcal) vaccines has been reviewed by Morley and Pollard (2002) and by Jódar et al. (2002)

PNEUMOCOCCAL MENINGITIS

Unlike Hib meningitis, the incidence of pneumococcal meningitis in the UK has not declined in recent years. In countries that have introduced conjugated Hib vaccines, pneumococci are now the second most common cause of bacterial meningitis. Mortality remains high. Antibiotic resistance, not only to penicillin but also to chloramphenicol and third-generation cephalosporins, is becoming a serious therapeutic problem in many parts of the world (Jacobs and Appelbaum 1995; Tomasz 1995).

Rapid progress in the development of conjugated pneumococcal polysaccharide vaccines offers good prospects for reducing the overall incidence of invasive pneumococcal disease and more modest but still interesting possibilities for reducing the incidence of pneumococcal meningitis. For all these reasons, pneumococcal meningitis is an extremely important condition and will remain so for the foreseeable future.

Epidemiology

Streptococcus pneumoniae causes bacteremia and meningitis at all ages, but attack rates are highest in infants, falling to low levels in children and young adults. Bacteremia rates then rise again to very high levels in the elderly, though rates of meningitis do not (Figure 9).

Meningitis occurs in about one-sixth of all invasive pneumococcal infections. The highest meningitis attack rate occurs in the first week of life, when the invading organisms are probably acquired from the maternal birth canal. Males are affected more often than females and infection is more common in the winter months. In the UK, pneumococcal meningitis attack rates have remained fairly constant over the period 1991–2000 at around 0.5–0.6 per 100 000 of the total population per annum (Aszkenasy et al. 1995; PHLS unpublished data).

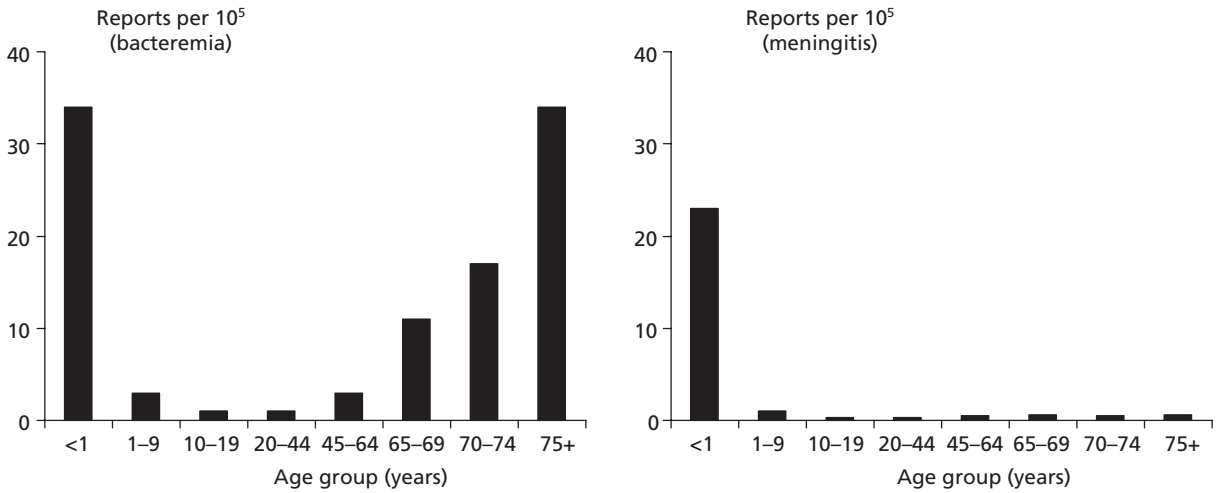

Figure 9 *Age incidence of* **(a)** *pneumococcal bacteremia and* **(b)** *meningitis: England and Wales, 1992.*

RISK FACTORS

Though age is the most important determinant of pneumococcal meningitis, patients with pneumococcal meningitis often have a pre-existing medical condition; recognized associations include splenectomy, thalassemia, sickle cell disease, alcoholism, myeloma, hypogammaglobulinemia, and complement deficiency. In the USA, rates of pneumococcal meningitis are much higher in nonwhites, though whether this is associated in part with socioeconomic factors is not clear.

Though pneumococci usually gain access to the subarachnoid space via the bloodstream, they may also spread directly from adjacent tissues, such as an infected paranasal sinus, the middle ear, or from a more distant focus of infection such as the lung. Recently it has been recognized that the risk of pneumococcal meningitis may be raised in recipients of some types of cochlear implants. Pneumococcal meningitis may follow any breach of the integrity of the subarachnoid space; this occurs most frequently following trauma (road accidents, etc.) resulting in dural tear. Pneumococcal meningitis following extrameningeal pneumococcal infection elsewhere in the body (and particularly pneumonia or endocarditis) carries a poor prognosis (Lepper and Dowling 1951; Bohr et al. 1985).

Only a small number of the 84 pneumococcal serotypes (1–9, 12, 14, 18, 19, 22, 23) are responsible for most invasive pneumococcal disease. Particular serotypes may be associated with central nervous system infection, some with a higher case fatality rate.

Clinical presentations and outcome

Clinical presentations depend on age but are similar to those of other types of acute pyogenic meningitis. Typically the presentation is abrupt, but symptoms may develop over several days. At presentation, patients with pneumococcal meningitis tend to be iller than those with Hib or meningococcal meningitis; fits are commoner (Pedersen and Henrichsen 1983) and there may be focal neurological signs, especially cranial nerve palsies. Comatose or semicomatose patients are more likely to have pneumococcal than meningococcal meningitis (Carpenter and Petersdorf 1962). Petechial rashes, though much less frequently encountered than in meningococcal meningitis, may also occur, especially in asplenic patients. In the neonatal period, clinical presentations are similar to those seen in other types of neonatal bacterial meningitis.

Elderly patients, patients with impaired consciousness or with convulsions on admission, and patients with a distant focus of pneumococcal infection are all more likely to die. Deafness and other permanent neurological sequelae are encountered frequently in survivors of pneumococcal meningitis.

Morbidity and mortality in pneumococcal meningitis are much worse than in Hib or meningococcal meningitis. Sangster and colleagues reported a mortality rate of 25 percent in the UK in the 1970s (Sangster et al. 1982) and mortality rates of 40–50 percent are commonplace in pneumococcal meningitis in tropical Africa (Greenwood 1987). Case fatality rates are still probably in excess of 20 percent in the UK and higher in the elderly. A similar proportion of survivors are left with moderate or severe neurological disability. This may be related in part to the much higher CSF bacterial load in pneumococcal meningitis than in meningococcal meningitis (Hassan-King et al. 1984) and to the long persistence of live bacteria within the subarachnoid space after the commencement of antibiotic treatment (Greenwood et al. 1986), the latter possibly associated with the particular capacity of pneumococci to induce a viscid, gelatinous exudate into which antibiotic penetration is poor.

Treatment

ANTIBIOTICS

Until quite recently, pneumococci were sensitive to penicillin in almost all parts of the world. When the causative strain is fully sensitive (minimum inhibitory concentration (MIC) 0.1 μg/ml), benzylpenicillin in large doses remains the antibiotic treatment of first choice. Schmidt and Sesler (1943) were the first to report penicillin resistance. Multiple antibiotic-resistant strains are now encountered frequently in the USA, Australia, New Guinea, and South Africa (Lister 1995; Schwartz and Tunkel 1995). The prevalence of moderately penicillin-resistant strains (MIC 0.1–1.0 μg/ml) varies widely from country to country; in England and Wales it was 2 percent in 1995 (Aszkenasy et al. 1995) rising to 7 percent in 2000 (PHLS unpublished data), 25 percent in the USA, and 40–45 percent in Spain and South Africa (Friedland and Klugman 1992a; Tomasz 1995); in almost all countries the prevalence of moderately resistant and of highly resistant strains (MIC 2.0 μg ml/1 or greater) is increasing (Breiman et al. 1994). Penicillin resistance may have arisen through transfer of genetic material from strains of *Streptococcus mitis* (Coffey et al. 1995).

Pneumococci resistant to third-generation cephalosporins have been documented in the USA and in South Africa (Friedland and Klugman 1992a; Tenover et al. 1992). Detection of resistance to β-lactam antibiotics (Tenover et al. 1992) is not merely of interest in the laboratory: it is associated with treatment failure (Bradley and Connor 1991; Sloas et al. 1992). In countries with a high prevalence of low-level pneumococcal penicillin resistance, third-generation cephalosporins such as cefotaxime and ceftriaxone are widely used as empirical agents of first choice in bacterial meningitis. However, as the level of resistance to penicillin rises, cephalosporins and chloramphenicol lose their efficacy (Friedland and Klugman 1992b; Lister 1995). Antibiotic treatment options for penicillin and cephalosporin-resistant pneumococcal meningitis have been reviewed (Jacobs and Appelbaum 1995; Lister 1995; Schwartz and Tunkel 1995). Chloramphenicol should not be used, even though strains may appear sensitive in the laboratory. Vancomycin, with or without the addition of rifampicin, becomes the antibiotic of choice, even though it penetrates poorly into the CSF. McCracken's group advocate the use of vancomycin accompanied by cefotaxime or ceftriaxone, and with the addition of dexamethasone for the empirical treatment of suspected pneumococcal meningitis (Paris et al. 1995). To cover meningococci, benzylpenicillin or a cephalosporin should always be incorporated into any empirical treatment regimen for bacterial meningitis when the causative organism has not been identified. Though data are scanty, most experts treat pneumococcal meningitis with parenteral antibiotics for at least 10–14 days (McCracken et al. 1987; O'Neill 1993).

STEROIDS

Dexamethasone reduces morbidity in pneumococcal meningitis. A recent pan-European study has demonstrated significantly improved outcome when dexamethasone is given before or with the first dose of parenteral antibiotic in pneumococcal meningitis in adults (de Gans and de Beek 2002; Tunkel and Scheld 2002). If a number of practical issues can be addressed, this may be advocated more widely as part of management protocols if cases of suspected pneumococcal meningitis in adults can be identified reasonably accurately.

MANAGEMENT OF CONTACTS

Contact with a case of pneumococcal meningitis does not usually confer an increased risk of disease. Neither antibiotic prophylaxis nor vaccination is normally recommended to protect intimate contacts of patients with pneumococcal meningitis.

RECURRENT PNEUMOCOCCAL MENINGITIS

The occurrence of a second episode of pneumococcal meningitis in a patient should raise the strong suspicion of a dural tear and there is usually, but not always, a history of cranial trauma. Such patients should be referred to a neurosurgeon for evaluation. A few patients with a history of recurrent pneumococcal meningitis but without a dural defect respond poorly to pneumococcal capsular polysaccharides; usually they respond to conjugated pneumococcal vaccines.

Prevention

PNEUMOCOCCAL VACCINES

Pneumococcal capsular polysaccharides are major virulence determinants and are immunogenic; vaccines based on capsular polysaccharides have been used for more than 20 years. Multivalent vaccines are used because there are more than 80 serotypes and protection is serotype specific. Vaccines containing 6–14 common serotypes were used in the 1970s but were superseded by 23-valent vaccines in the 1980s. Though the frequency with which the different serotypes cause invasive disease varies from country to country and across different age groups (Scott et al. 1996), the currently available 23-valent polysaccharide vaccines offer a high degree of protection in most, if not all, countries.

Purified pneumococcal polysaccharides do not make ideal vaccines (Mitchell and Andrew 1995). In common with other bacterial polysaccharides, they are high-molecular-weight compounds with repeating structures that stimulate B lymphocytes directly without

Table 3 *Characteristics of T-cell-independent (TI) and T-cell-dependent (TD) antibody responses*

Characteristics	TI	TD
T cells required	–	+
Ontogeny of response	Late	Early
Induction of memory	–	+
Isotype restriction	+	–
Affinity maturation	–	+

Purified polysaccharides are converted from TI to TD antigens by conjugation to carrier proteins, e.g. tetanus toxoid.

stimulating T cells. T-cell-independent antigens have a number of defects as vaccine candidates (Table 3).

In older children and adults, the antibody induced by plain polysaccharide vaccines does not persist, leading to waning of protection over time. The capacity of the 23-valent vaccine to induce good immune responses declines progressively after the age of 60–65 years, particularly in patient groups at increased risk of invasive disease, including those with asplenia, hyposplenism, and a variety of immunodeficiency conditions, including HIV infection. Patients with AIDS and CD4 counts greater than 500/mm^3 respond well, those with lower counts less satisfactorily (Rodriguez-Barradas et al. 1992). Thus, the groups at highest risk of invasive pneumococcal disease are the most difficult to protect with purified polysaccharide vaccines. Nevertheless, the 23-valent polysaccharide vaccine has been recommended for a wide variety of groups at increased risk of invasive or severe disease. These include patients aged over 2 years with functional or anatomical asplenia or hyposplenism (including sickle cell disease), patients with AIDS (regardless of the stage of illness) and other immunodeficiency states, malignancies, chronic respiratory, renal, and liver diseases, and some metabolic diseases such as diabetes (Department of Health 1996). Plain polysaccharide vaccines offer healthy elderly people protection against invasive pneumococcal disease (and may thereby protect against meningitis) but may not protect against nonbacteremic pneumonia.

Vaccination does not protect against recurrent pneumococcal meningitis associated with dural tears; repair of the defect is the only effective treatment known. Revaccination with 23-valent pneumococcal polysaccharide vaccine within 18 months of a previous dose is associated with a higher incidence of side effects (Borgono et al. 1978), but there is no evidence that revaccination after 4–6 years causes increased side effects (Kaplan et al. 1986a; Mufson et al. 1991).

Conjugated pneumococcal polysaccharide vaccines have now been subjected to clinical trials. A study of a seven-valent conjugated pneumococcal vaccine in infants in California showed excellent protection against invasive disease (Black et al. 2000). Similar conjugated vaccines containing a greater number of pneumococcal serotypes are expected to become available shortly. They should give rise to long-lasting, though serotype-specific, protection at almost all ages. Conjugated pneumococcal vaccines also reduce nasopharyngeal carriage of homologous pneumococcal serotypes (Dagan et al. 1996) and thus a herd immunity effect may occur if such vaccines were to be widely used in children. Pneumococcal conjugated vaccines will be expensive and may need to be tailored to the serotypes prevalent in different countries.

Attempts to produce pneumococcal vaccines based on surface-exposed proteins expressed by all pneumococci, regardless of serotype, have so far been unsuccessful. Research is continuing on a number of candidate proteins, including pneumolysin, neuraminidase, pneumococcal surface protein A, and a 37-kDa outer-membrane protein. Such outer-membrane proteins may become constituents of pneumococcal vaccines in the future, but are unlikely stand-alone vaccine candidates (Mitchell and Andrew 1995).

Pneumococcal meningitis in the first month of life is probably not preventable by infant vaccination, even at birth. Alternative strategies, such as maternal immunization during or before pregnancy, or passive protection of newborn infants with immunoglobulin followed by active immunization at a later date, may need to be considered.

ANTIBIOTIC PROPHYLAXIS

Long-term oral penicillin or amoxycillin prophylaxis has been used in an attempt to reduce the risk of invasive pneumococcal disease in patients at increased risk, but there is no evidence that prophylactic antibiotics can reduce the risk of primary or recurrent pneumococcal meningitis.

Haemophilus influenzae type b meningitis

EPIDEMIOLOGY

Before the widespread introduction of effective vaccines, Hib was the commonest cause of bacterial meningitis in children under the age of 5 years in almost all countries; in countries such as the USA, Australia, Brazil, and Zaire, it was the commonest cause of bacterial meningitis in the population as a whole. Within countries, attack rates of invasive Hib disease vary widely. In the UK, attack rates of 24–36 per 10^5 children under 5 years of age were observed in six regions in 1990–92 (Anderson et al. 1995), with almost 90 percent of invasive *H. influenzae* infections occurring in children under 5 years of age.

In contrast, attack rates of Hib disease in 'native American' and Australian aboriginal populations of 150–450 per 10^5 children aged under 5 years, i.e. rates ten-fold higher than in Europeans, have been recorded (Bijlmer 1991). In the USA, higher disease rates in

blacks than whites may have been due to socioeconomic rather than racial factors (Cochi et al. 1986). Though Hib meningitis has a relatively low case fatality rate in economically advanced countries (3–5 percent), high fatality rates (20–30 percent) are common in tropical Africa (Bijlmer 1991).

Before vaccination was introduced, most UK cases of Hib meningitis occurred in infants, with a peak attack rate in the 6–11 months age group (Anderson et al. 1995); in population groups with very high disease attack rates, peak attack rates occurred in children under 6 months old (Bijlmer 1991). A peak of disease at such an early age presented problems in the deployment of vaccines.

The increasing incidence of invasive Hib disease in the USA and the UK in the 1970s and 1980s was probably due to social changes as well as more accurate diagnosis. Attendance at daycare centers or preschool nurseries may have conferred an increased risk of disease; conversely, breast feeding was protective (Redmond and Pichichero 1984; Cochi et al. 1986).

Bacteriology and immunology

Acapsulate strains of *H. influenzae* are part of the human nasopharyngeal commensal flora. They are of low pathogenicity and cause mainly localized infections in the respiratory tract in young children and in patients with pre-existing disease.

A small minority of *H. influenzae* strains possess a polysaccharide capsule, of which structural variants define six serotypes designated a–f. The type b polysaccharide is a polymer of ribose and ribitol phosphate (polyribosephosphate (PRP)). Before vaccination was introduced, type b strains (Hib) were responsible for more than 95 percent of invasive hemophilus disease. Meningitis was the commonest clinical manifestation, followed by epiglottitis, bacteremia without localizing features, cellulitis, pneumonia, and septic arthritis (Anderson et al. 1995). Most, if not all, invasive Hib disease is accompanied by a bacteremic phase.

Hib is carried mainly by children, but the overall carriage rate in unimmunized populations is only 1 percent in children under 6 years of age; the peak of carriage occurs in children aged 24–36 months (Howard et al. 1988).

The early classical investigations of Fothergill and Wright (1933) showed that blood samples from children aged between 3 months and 3 years lacked bactericidal activity against Hib, in contrast to samples from neonates, older children, and adults. Subsequently Alexander et al. (1942) showed that administration of Hib antiserum caused a substantial increase in the phagocytosis of Hib bacteria in the subarachnoid space, suggesting the importance of opsonizing type-specific antibodies.

The carriage rate of Hib strains in young children is so low that many who acquire antibodies to PRP must do so without exposure to Hib strains. Their protective antibodies probably result from exposure to heterologous bacteria that produce polysaccharides with antigenic determinants identical to those on PRP. Amongst several other bacterial species, *Escherichia coli* K100 expresses an almost identical polysaccharide and, if fed to adult volunteers or laboratory animals, induces antibodies that show bactericidal and opsonic activity against Hib (Schneerson and Robbins 1975).

Bacteremia precedes Hib meningitis, epiglottitis, and the other invasive Hib syndromes. Why the bacteria localize in the meninges, or other organs, is not well understood (Moxon 1992). Experiments in an infant rat model indicate that the intensity of bacteremia may be an important factor in the development of meningitis (Moxon and Ostrow 1977).

Clinical features

The disease may develop insidiously over 24–48 h or it may present more abruptly. Most cases are in infants, who often start by being 'snuffly.' Fever and vomiting are common, early, nonspecific symptoms (Haggerty and Ziai 1964) that may be accompanied by failure to feed, pallor, irritability, and persistent crying. As the infection progresses, shock may supervene and the level of consciousness may become clearly depressed with listlessness and inability to maintain eye contact; infants may be extremely ill by the time the diagnosis is made. Seizures occur in a minority of cases (Feigin 1987), more commonly in Hib and pneumococcal meningitis than in meningococcal meningitis.

In older children, the more traditional symptoms of meningitis – headache, neck stiffness, and photophobia – may be encountered.

Treatment

Intravenous chloramphenicol replaced ampicillin when resistance of Hib to the latter due to β-lactamase production began to increase; in 2002 it was 15 percent in the UK but is higher elsewhere. Chloramphenicol fell into disuse partly because of a small but increasing percentage of resistant strains (1–2 percent), but also because of fears of irreversible bone-marrow suppression. It has been replaced by third-generation cephalosporins. Cefotaxime and ceftriaxone are superior to cefuroxime; the latter takes longer to sterilize the CSF and is associated with a higher incidence of hearing loss (Schaad et al. 1990). Ceftriaxone may be given as a single daily dose and, in carefully selected patients with milder illness, it is suitable for outpatient completion of a course of parenteral antibiotic treatment for bacterial meningitis. Antimicrobial treatment of Hib meningitis

should normally be continued for 7–10 days (McCracken et al. 1987; O'Neill 1993).

Administration of dexamethasone to children with Hib meningitis before, or at the same time as, the first dose of antibiotic is given reduces the incidence of neurological sequelae, principally deafness (Lebel et al. 1988; Feigin et al. 1992; Schaad et al. 1993; McIntyre et al. 1997). Steroids probably act by blocking the inflammatory cascade induced by the release of endotoxin into the subarachnoid compartment. If given after the first dose of antibiotic, they are ineffective.

Susceptible contacts of cases of invasive Hib disease run a considerably increased risk of developing Hib disease in the weeks after the contact. The degree of increased risk depends on the intimacy of the contact; household contacts are at greater risk than daycare-center or preschool playgroup contacts. Unvaccinated close contacts aged up to 4 years should be offered rifampicin prophylaxis and an immediate course of Hib vaccine: three doses if aged under 1 year or one dose if aged 13–48 months. Adult contacts do not need Hib vaccine and require chemoprophylaxis only if an unimmunized contact aged under 4 years is in the household (Cartwright et al. 1994).

Vaccines

The first Hib vaccines consisted of purified type b capsular polysaccharide (PRP) and suffered from all the defects of T-cell-independent antigens (see Table 3). In spite of their disadvantages, PRP vaccines were widely used in the USA in the 1980s to immunize children aged over 18 months and they did reduce the incidence of invasive Hib disease albeit modestly.

Conjugated polysaccharides are T-cell-dependent antigens and their introduction as vaccines changed the situation dramatically, since such vaccines are immunogenic even in infants under 3 months of age. They induce high-avidity IgG antibodies and long-term immunity.

The impact of Hib vaccination is almost immediate, because almost all invasive Hib disease occurs in infants and very young children. In England and Wales, Hib vaccines were introduced in October 1992 and by 1994 there was a two-thirds reduction in invasive Hib disease and a continuing falling trend. Invasive Hib disease in unimmunized older people also fell, due to a reduction in the prevalence of Hib nasopharyngeal carriage and the beneficial effect of herd immunity

Hib vaccine is offered to all UK infants aged 2, 3, and 4 months and to selected at-risk groups such as asplenic adults. For financial and logistic reasons, these highly effective vaccines have hardly been used in poorer countries, where the need is greatest (Booy 1998).

Over the past 3 years there has been some evidence in the UK of a slight resurgence of invasive Hib disease (Figure 10) and it is now planned to offer a fourth,

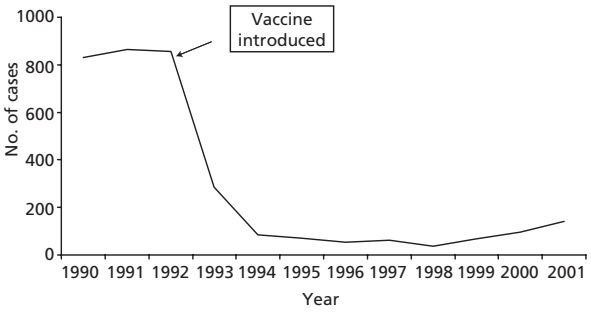

Figure 10 *Invasive* Haemophilus influenzae *type b (Hib) infections, England and Wales: Combined Health Protection Agency (HPA) Haemophilus Reference Unit & HPA Communicable Disease Surveillance Center data.*

reinforcing dose of Hib vaccine to all children. This will be given at the same time as the preschool doses of diphtheria, tetanus, and polio vaccines.

NEONATAL MENINGITIS

Neonatal bacterial meningitis (bacterial meningitis in the first month of life) is rare but serious, with a mortality up to 30–40 percent and permanent sequelae in up to 30 percent of survivors. The causative organisms are different from those of bacterial meningitis at other ages, since most bacterial meningitis in this age group is due to organisms derived from ascending infection in utero or from the birth canal during delivery (de Louvois 1994). Occasionally, outbreaks occur in hospital nurseries. Neonatal bacterial meningitis is almost always preceded by bacteremia. In the UK, the principal causative organisms are gram-negative enteric bacilli and group B streptococci. The latter can cause early-onset or late-onset disease as long as 3–4 months after birth. Other bacteria, including pneumococci, *Listeria monocytogenes*, meningococci, other streptococci, and *Staphylococcus aureus*, can also cause neonatal meningitis.

The overall rate of infection in the UK is about 0.25 per 1 000 live births (de Louvois 1994), whereas in the USA it may be two to three times higher (Riley 1972). Twenty years ago, gram-negative enteric bacteria were the most frequent cause of neonatal meningitis in the USA, but more recently, group B streptococci have predominated. The neonatal sepsis rate with group B streptococci is much higher in the USA than in the UK. In the USA, screening late in pregnancy and treatment of carriers has been advocated, but such a policy presents considerable practical problems (Towers 1995).

Prematurity, low birth weight, prolonged rupture of membranes, and prolonged labor all increase the risk of neonatal meningitis. Babies born to mothers who are pyrexial during labor are also at risk, and some infections are acquired in utero.

It is unclear why particular babies develop meningitis. Almost all strains of *E. coli* that cause neonatal

meningitis express the K1 capsular antigen (Mulder and Zanen 1984). Group B streptococci of type III are more commonly isolated from cases of neonatal meningitis than other group B streptococci, and both neonatal and maternal antibody levels to these organisms are lower in affected than in control babies.

Neonates frequently show little specific evidence of meningeal irritation. They may be 'jittery' or may present with listlessness, pallor, crying that may be high-pitched, failure to feed, vomiting, and sometimes jaundice; respiration, heart rate, and temperature control may become unstable. These nonspecific symptoms may progress to more obvious depression of consciousness. Raised intracranial pressure, as evidenced by a bulging fontanelle, occurs late, and only in a minority of cases.

Blood cultures are part of the standard investigation of any sick baby. If meningitis is suspected, lumbar puncture should be considered at an early stage, though failure to detect an abnormality on initial examination should never lead to the withholding of antibiotic treatment. Infection at another site such as the urinary tract should be excluded.

Once meningitis is confirmed, the choice of antibiotics depends on the causative organism. A combination of benzylpenicillin and gentamicin is often used while the results of blood and CSF culture are awaited and can be continued if group B streptococci are isolated. If a gram-negative bacillus is isolated, a combination of a cephalosporin and an aminoglycoside may be appropriate, but treatment should be guided by the antibiotic sensitivity of the particular organism.

TUBERCULOUS MENINGITIS

Tuberculous meningitis is rare. In the UK there are around 100 cases each year, the majority in people from the Indian subcontinent. After a steady decline over many years in the incidence of tuberculous disease, there has been a rising trend in notifications over the period 1988–2000 (9.4–12.0 cases per 10^5 per annum). In the USA, tuberculous meningitis is a well-recognized late complication of AIDS (Bishburg et al. 1986); atypical mycobacteria are sometimes responsible. So far, there is little evidence of an overlap between tuberculosis and AIDS in the UK.

Tuberculous meningitis probably always arises as a result of dissemination of tubercle bacilli from a distant focus of infection, often the lung. The disease is caused by liberation of tubercle bacilli from subpial tuberculomata into the subarachnoid space (Rich and McCordock 1933). Postmortem examination confirms the gelatinous nature of the exudate, particularly around the base of the brain, consistent with the high incidence of cranial nerve palsies seen in tuberculous meningitis.

The disease almost always presents insidiously with persistent fever and increasing headache over a period of weeks or months, but, rarely, the presentation may be acute. The cellular exudate in the CSF is most frequently lymphocytic, but it may be mixed, and the protein concentration is often very high (2–3 g/l). The CSF:blood glucose ratio is usually, but not always, reduced. In the majority of cases tubercle bacilli are not seen on direct microscopy. The culture of CSF for tubercle bacilli should be extended because about 10 percent of cultures will become positive only after 6 weeks. A mycobacterial PCR test is now available from the Regional Centres for Mycology in the UK for the investigation of suspected tuberculous meningitis.

Plain chest and abdominal radiographs may reveal a primary tuberculous focus, so increasing suspicions of tuberculous meningitis. Computed tomography and nuclear magnetic resonance imaging of the cranium are useful investigative techniques (Berger 1994). Since direct microscopy is insensitive, empirical antituberculous treatment may have to be started if the clinical picture is strongly suggestive. Treatment is usually based on a combination of rifampicin, isoniazid, and pyrazinamide, but the use of steroids is controversial. The prevalence of isoniazid and multidrug resistance has remained stable between 1994 and 1999 (Djuretic et al. 2002). In the UK, tuberculous meningitis is usually managed by chest physicians because of their familiarity with antituberculous therapy.

OTHER TYPES OF BACTERIAL MENINGITIS

In this brief review it is not possible to list all the more unusual types of bacterial meningitis. *Listeria monocytogenes* continues to cause a small number of cases of meningitis, mainly in the elderly and in dependent patients (Calder 1997). Fulminant listeria meningitis is accompanied by a high case fatality rate. Three nonviral causes of aseptic (lymphocytic) meningitis should be briefly mentioned – Lyme borreliosis (Pachner 1995), syphilis (Lukehart et al. 1988), and primary amebic meningoencephalitis (Carter 1968). These may all present acutely, but all are very rare in the UK. The history, such as that of a tick bite in Lyme meningitis, or of swimming in warm water before amebic meningoencephalitis, may provide diagnostic clues.

For cryptococcal and fungal meningitis see the Medical Mycology Volume, Cryptococcosis.

Introduction	1	Spinal epidural abscess	12
Intracranial abscess (brain abscess)	1	References	14
Subdural empyema and intracranial epidural abscess	9		

INTRODUCTION

Focal pyogenic infections of the central nervous system (CNS) are life-threatening conditions that require treatment both surgically and with antibiotics. The most common three conditions are brain abscess, subdural empyema, and spinal abscess; however, these serious infections are uncommon with a cumulative lifetime incidence of approximately 1 percent for brain abscess.

Until the last quarter of the nineteenth century successful treatment for a brain abscess, commonly traumatic in origin, was rare. The first surgeon said to operate successfully on an otitic abscess was a Frenchman, Morand, in 1752 (Canale 1996). Further occasional successes were reported over the next hundred years (Weeds 1872). In 1893, William MacEwan, a surgeon from Glasgow, published a monograph that included details of his cases successfully treated by surgery (MacEwan 1893). Of 19 patients with brain abscess, 18 survived surgery, and this was a remarkable achievement at the time. By the beginning of the twentieth century surgical drainage of brain abscess was accepted as the treatment of choice.

Antibiotics began to play a part in treatment of abscesses as they were discovered throughout the first part of the twentieth century (Canale 1996). Mortality still remained high, however, until antibiotics such as penicillin and chloramphenicol were more widely used. The advent of better imaging techniques such as CT scans, and improved surgical techniques have been responsible for improving the outcome of these serious infections. In the field of microbiology an important advance was the upsurge of interest in obligate anaerobes and their role in human disease (Heineman and Braude 1963). The importance of anaerobic bacteria in CNS infections was emphasized and allowed antibiotic regimens to be tailored accordingly (De Louvois et al. 1977a; Ingham et al. 1977). Further advances which have been made in the last 10 years include the wider availability of MRI scanning which is able to pick up abscesses in the early stages, minimally invasive surgical techniques for abscess drainage, and new antimicrobial agents with better activity and CNS penetration.

INTRACRANIAL ABSCESS (BRAIN ABSCESS)

Epidemiology

Brain abscess accounts for about one in 10 000 general hospital admissions in the UK and USA each year and this incidence has remained relatively stable in the antibiotic era. Approximately four to ten cases are seen annually in neurosurgical units of developed countries each year (Donald et al. 1990; O'Donoghue et al. 1992; Richards et al. 1990). Some series have noted a slight increase in cases in recent years (Neilsen et al. 1982; Chun et al. 1986) that may be accounted for by better diagnostic techniques. Conversely other series have noted a decline in incidence (Nicolosi et al. 1991).

Mortality rates have ranged from 30 to 60 percent until the late 1970s (Garfield 1969) when the overall mortality dropped, and is now 0–24 percent (Seydoux and Francioli 1992; Donald et al. 1990; Ibrahim et al. 1990). This improvement has been attributed to better

radiological techniques to diagnose and localize the abscesses, better surgical techniques, and new more effective antimicrobial agents (Mampalam and Rosenblum 1988).

A male predominance exists in most series, with brain abscesses being two to three times more common in men than in women in most recent series (O'Donoghue et al. 1992; Seydoux and Francioli 1992). The median age is said to be 30–40 years; however, this will vary with predisposing factor and site of abscess. Incidence among other countries varies greatly and is related to differences in predisposing factors and underlying medical conditions (Ibrahim et al. 1990; Lu et al. 2002); for example, in China, 65 percent of brain abscesses are secondary to otitis media, while only 0.5 percent are associated with sinusitis (Yang 1981). In European countries, 20–40 percent occur in association with otitic infections and 15–25 percent with sinusitis (Bradley and Shaw 1983; Van Alphen and Driessen 1976).

Overall about 25 percent of brain abscess occur in children mostly in the 4–7 year age group (Neilsen et al. 1982; Kaplan 1985). Neonatal brain abscess is rare and is usually associated with gram-negative bacillary meningitis (Renier et al. 1988).

Changes in the epidemiology and causative organisms have occurred in recent years with the advent of HIV-related diseases and a larger group of immunosuppressed patients for example, following bone marrow transplant. In a series of bone marrow transplants, brain abscess was found to occur in one of every 49 patients (Hagensee et al. 1994). Solid organ transplant recipients are at increased risk of developing CNS infections – approximately 2–12 percent of solid organ recipients will develop CNS infections including brain abscess (Selby et al. 1997; Conti and Rubin 1988).

Predisposing conditions

The most common predisposing conditions are those which form a contiguous focus of infection, in other words infection in the ear, sinuses, or teeth (Table 1). Ear infections, such as acute or chronic otitis media, or mastoiditis have been most commonly reported in series with numbers ranging from 14 up to 60 percent (Lu et al. 2002; Alderson et al. 1981; Chun et al. 1986; O'Donoghue et al. 1992; Yang 1981; Ariza et al. 1986). The numbers vary with country of origin; overall, ear (otogenic) infections are the most common factor associated with contiguous spread.

Table 1 *Brain abscess: predisposing conditions and site of abscess*

Predisposing condition	Site of abscess
Chronic ear infection, mastoiditis	Temporal lobe, cerebellum
Paranasal sinusitis	Frontal lobe
frontoethmoidal	frontal
sphenoidal	temporal
Dental infection	Frontal lobe
Trauma or post surgical	Related to wound/operation site
Hematogenous spread	Middle cerebral artery distribution

The age incidence of otogenic brain abscesses shows a bimodal distribution with cases peaking in the pediatric age group then again in the over-40s (Small and Dale 1984). Otogenic brain abscess may be decreasing in relative frequency, as shown by a series from Sweden where otogenic abscesses accounted for only 7.4 percent (Schliamser et al. 1988). Areas where otitis media is neglected or therapy is delayed still see the serious complications associated with this condition. A series from Saudia Arabia found that chronic otitis media and sinusitis accounted for 57 percent of cases (Ibrahim et al. 1990).

The majority of otogenic brain abscesses (35–75 percent) are located in the temporal lobe (Figure 1). The cerebellum is the next most common site (20–30 percent) and otogenic infections account for 85–99 percent of cerebellar abscesses. Most of these are solitary lesions (Wispelwey et al. 1997).

Sinus disease is generally the next most common predisposing factor and is reported to account for 10–36 percent of cases in recent series (Alderson et al. 1981; Chun et al. 1986; Lu et al. 2002), but these figures may be showing a decrease as the early use of antibiotics may modify the disease process. Sinus disease is a major predisposing factor for subdural empyema. The age group most commonly affected is 10–30 years (Bradley et al. 1984). Generally cases of frontoethmoidal sinusitis will localize to the frontal lobe, and the rarely seen condition of sphenoidal sinusitis will produce abscesses in the frontal or temporal lobes (Table 1).

Dental infections as a source for intracranial abscess (odontogenic) are much less common but may lead to cavernous sinus thrombosis, subdural empyema, and meningitis. Rarely a brain abscess may complicate cavernous sinus thrombosis, but it is not clear whether the abscess develops as a coexisting event rather than as a consequence of the thrombosis (DiNubile 1988).

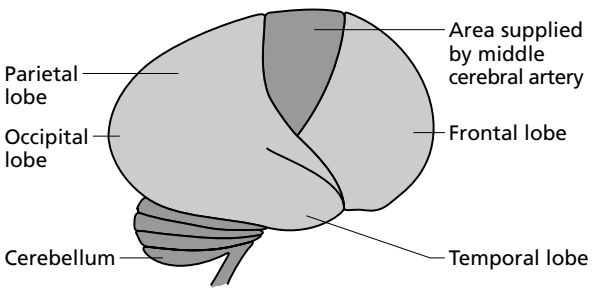

Figure 1 *Diagram of the brain showing the anatomical areas where abscesses occur.*

Odontogenic abscesses were found in six of 45 patients in one series (Chun et al. 1986), and in only five of 81 in another (Small and Dale 1984). Infection of the molar teeth is more likely to lead to intracranial complications as the bacteria can spread between the muscle planes to the base of the skull. Unrecognized dental infection may account for some abscesses where no other clear predisposing factor is evident and the bacteria cultured resemble those of dental origin (Ingham et al. 1978). Odontogenic abscesses are generally found in the frontal lobe. An odontogenic source should be considered in patients presenting with septic cavernous sinus thrombosis and any abscess of uncertain origin.

Hematogenous spread from a distant focus of infection usually causes multiple abscesses in the region of the middle cerebral artery distribution and at the junction of the gray matter and white matter (Figure 1). Hematogenous abscesses account for around 25 percent of cases in most series (Chun et al. 1986; Yang 1981). Endocarditis and pyogenic pulmonary infections such as lung abscess, bronchiectasis, empyema, and cystic fibrosis are common predispositions. Chronic suppurative lung disease has in the past accounted for one half of all hematogenous cases, but now may be becoming less common as a predisposing factor, and a study shows the number of cases dropping from 18 percent in the early 1970s to 2 percent in the 1980s (Mampalam and Rosenblum 1988). Congenital cyanotic heart disease, commonly seen as a predisposing factor in children, and pulmonary arterio-venous (AV) malformations increase the risk of hematogenous spread to brain and may account for 3–13 percent of cases (Park and Neches 1993). A report of 50 cases from India had 18 percent caused by congenital heart disease and 12 percent by pulmonary disease (Lakshmi et al. 1993). Other remote foci of infection which may lead to brain abscess are septic foci in abdomen, pelvis, urinary tract, or bones. Rarely cases have been reported following injection of bleeding varices (Cohen et al. 1985) and following tongue piercing (Martinello and Cooney 2003).

Endocarditis is an important infection that may be complicated by brain abscess; 1–5 percent of cases may go on to develop brain abscess (Lerner 1985). The lesions are mostly multiple. Endocarditis and subsequent central nervous system infection is increasingly being seen in injecting drug users (Tunkel and Pradhan 2002).

Hereditary hemorrhagic telangiectasia is a condition that carries a significant risk for developing brain abscess; this complication may develop in 1–6 percent of patients (Press and Ramsey 1984) most often in the third to fifth decade of life. AV malformations may occur in the brain as a result of this condition, providing a nidus for bacteria.

Trauma, either accidental injury to the brain or post neurosurgical procedure is an important risk factor, but less common than those listed above. Clean neurosurgical procedures, for example, craniotomy not associated with trauma, is complicated by infection in 0.6–1.7 percent of cases (Tenney 1986). Most of these cases are meningitis, about 10 percent are brain abscess.

Cases ascribed to trauma in published series vary greatly and will depend on epidemiological factors and availability of specialist neurosurgical units. Published figures for the incidence of cases related to trauma range from 12 to 37 percent (Schliamser et al. 1988; Lu et al. 2002; Ariza et al. 1986; O'Donoghue et al. 1992) and may be showing an increase as abscesses secondary to chronic lung disease and sinusitis decline. Accidental trauma, such as head injury with skull fractures and penetrating wounds with sharp objects, for example darts, are all reported to cause brain abscess. Abscesses may develop up to 113 days after the injury (Patir et al. 1995).

Bacterial meningitis as a predisposing factor for intracranial abscess is quite unusual, but may predispose to subdural empyema. The exception is in the neonatal age group when gram-negative bacilli may cause focal intracranial sepsis after meningitis (Renier et al. 1988).

Over the last decade there has been an increase in intracranial sepsis seen in immunosuppressed patients. This is an enlarging group of patients who may be immunosuppressed by disease such as HIV-related disease, by hematological malignancies and their treatment, and by immunosuppression following solid organ transplant. A varied range of microorganisms may be seen in these patients to include bacteria, fungi, and protozoa (Calfee and Wispelwey 2000).

In most cases of intracranial sepsis the primary source can be found, but in approximately 15–20 percent of cases no predisposing factor is identified. These are referred to as cryptogenic abscesses.

Pathogenesis and pathophysiology

The factors necessary for establishment of a brain abscess are a source of virulent microorganisms and the presence of ischemic or devitalized brain tissue. There may be a variety of primary foci and there is a close relationship between the primary focus and the bacterial flora isolated. Experimental evidence suggests that infection is difficult to establish in normal brain tissue (Molinari et al. 1973).

There are differences in the ability of microorganisms to produce brain abscess. Animal models of abscess formation studied *Escherichia coli* and *Staphylococcus aureus* injected into skin and brain tissue and found that the brain is much more susceptible to bacterial challenge than the skin with as few as 10^2 colony-forming units (cfu) of either organism resulting in abscess formation (Mendes et al. 1980). Capsular strains of *E. coli* were more virulent (Costello et al. 1983), the capsule of anaerobes such as *Bacteroides fragilis* may play a part in pathogenicity. Bacteria more commonly found in brain

abscess such as *Bacteroides fragilis* or *Streptococcus intermedius* failed to produce infection and abscess formation in an animal model (Onderonk et al. 1979). In most abscesses mixtures of organisms are found and the synergistic interactions undoubtedly play an important role in the pathogenesis of these mixed infections. The aerobic and facultative organisms may aid the anaerobes by using the available oxygen.

The role of other virulence factors in brain abscess formation has not been evaluated. Bacterial lipopolysaccharide has been studied in detail with regard to pathogenesis of bacterial meningitis, but similar studies looking at its effect on pathogenesis of brain abscess have not been done.

The development of a brain abscess from the earliest stages to the development of a capsule has been carefully studied (Britt et al. 1981) using an animal model and CT scanning. These are the stages that were described:

1. Early cerebritis days 1–3: There is a marked inflammatory infiltrate of polymorphonuclear cells, lymphocytes, and plasma cells from capillaries. Bacteria can be seen on Gram stain and there is marked edema of the white matter surrounding the lesion.
2. Late cerebritis days 4–9: A well-formed necrotic center has developed and enlarged and there is new vessel formation around the developing abscess.
3. Early capsule formation 10–13 days: The necrotic center has decreased slightly in size and there is development of a layer of fibroblasts around the center that will eventually form the capsule. The edema is diminishing.
4. Late capsule stage 14 days and later: The process continues with the development of the capsule.

Bacteriology of brain abscess

The range of bacteria isolated from intracerebral abscesses has undergone a marked change during the last 50 years. Several factors may account for this. There have been improvements in microbiology techniques especially anaerobic culture; increased use of antibiotics early in treating predisposing conditions, such as otitis media, may change the flora of the ear or render cultures negative; changes in patient susceptibility, for example, more immunocompromised patients; predisposing factors such as access to neurosurgery; and availability of laboratory facilities and anaerobic culture methods.

In the preantibiotic era the common isolates from brain abscess were *Staphylococcus aureus*, reportedly found in 25–30 percent of cases, streptococci in 30 percent, and coliforms in 12 percent: 50 percent of pus samples were culture negative (De Louvois et al. 1977a; De Louvois 1978). With improvements in anaerobic techniques the role of anaerobes has become apparent (Heineman and Braude 1963). Series from the UK have stressed the importance of anaerobes particularly in otogenic infections (O'Donoghue et al. 1992; Ingham et al. 1977; Donald et al. 1990; Richards et al. 1990). The site of the abscess and the predisposing conditions are important predictors of the likely organisms (Table 2). There seems to be a predominance of aerobic organisms reported but this varies with the center and anaerobes have been reported as being present in 33–60 percent of cases (Seydoux and Francioli 1992; Sofianou et al. 1996; Ariza et al. 1986; Chaudhry et al. 1998), higher numbers

Table 2 *Brain abscess: predisposing condition and likely bacterial isolates*

Predisposing condition	Likely bacterial isolates
Ear disease	Streptococci aerobic and anaerobic
	Bacteroides fragilis and other *Bacteroides* spp.
	Enterobacteriaceae especially *Proteus* spp.
	Pseudomonas aeruginosa
	Actinomyces spp.
Sinusitis	Microaerophilic and anaerobic streptococci
	Bacteroides spp.
	Fusobacterium spp.
	Haemophilus spp.
Dental infection	*Streptococci*
	Fusobacterium spp.
	Bacteroides spp.
	Actinomyces spp.
Hematogenous spread	
Congenital heart disease	Viridans streptococci
	Anaerobic, microaerophilic streptococci
	Haemophilus spp.
Lung disease	*Actinomyces* spp.
	Fusobacterium spp.
Endocarditis	Viridans streptococci
	Staphylococcus aureus
Immunosuppression	
HIV disease	*Listeria monocytogenes*
Neutropenia	Enterobacteriaceae
	Pseudomonas aeruginosa
	Streptococcus pneumoniae
	Nocardia spp.
	Mycobacteria
Trauma surgical	*Staphylococcus aureus*
	Propionibacterium
Trauma by penetrating injury	*Pseudomonas* spp.
	Clostridium spp.
	Enterobacteriaceae
Neonate	*Citrobacter diversus*
	Pseudomonas aeruginosa

being reported in later studies. This may reflect the increasing availability of anaerobic culture facilities and better diagnostic laboratory support. One recent study identified nine anaerobes in 18 patients, these included *Prevotella melaninogenicus*, *Bacteroides preacutus*, *Fusobacterium nucleatum*, and *Peptostreptococcus* spp. (Chaudhry et al. 1998). The samples were received in the laboratory within 30 min, inoculated into anaerobic broth and enriched thioglycollate broth which undoubtedly improved the isolation rate. Four out of six of their patients had chronic suppurative otitis media as the predisposing condition.

The bacteriology of otogenic abscesses can be complex with multiple isolates of bacteria being recorded (Alderson et al. 1981) and represent the microbial flora of a chronically infected ear, but usually with the exception of *Pseudomonas* spp. Isolates include gram-negative aerobic bacilli, such as *Escherichia coli* and *Proteus* spp., aerobic and anaerobic streptococci, and other anaerobes such as *Bacteroides fragilis*, other *Bacteroides* spp., *Eubacterium*, and *Clostridium* spp. It is unusual to find organisms normally associated with upper respiratory tract infection, such as *Haemophilus* spp. and pneumococci. The isolation rate of anaerobes does vary and Seydoux reported almost equal numbers of aerobes and anaerobes in his paper (Seydoux and Francioli 1992). *Fusobacterium* spp. were the most common anaerobes recovered, whilst viridans streptococci and *Streptococcus milleri* were the most common aerobic isolates.

The presence of anaerobes may be detected by noncultural methods such as gas-liquid chromatography (Donald et al. 1990); this investigation showed that 13 of 18 specimens of pus were found to be positive by this method.

Gram stain is an essential part of the investigation of brain abscess pus, particularly if antibiotics have been given. The morphology of bacteria seen on Gram stain will be helpful in choosing antibiotics especially if the cultures are subsequently negative (Lakshmi et al. 1993).

Actinomyces spp. are reported in mixed culture with other aerobic and anaerobic bacteria (Donald et al. 1990; Smego and Foglia 1998) and represent part of the normal flora of the mouth or respiratory tract. Actinomycosis is of course a recognized disease entity and may present with abscess formation in the central nervous system. Usually, in this condition *Actinomyces* spp. would be present either as a single isolate or in conjunction with associate anaerobic organisms.

A series from Taiwan (Lu et al. 2002) looked at isolates over two time periods. During the second time period there was an increase in aerobic gram-negative bacilli. Viridans streptococci and *Klebsiella pneumoniae* were the most common isolates from hematogenous spread. Nosocomial infections and traumatic infections showed an increase in the second time period.

In sinugenic brain abscess the bacteriology resembles that of sinugenic subdural empyema. *S. milleri* is the most common isolate and is often found in pure culture. Mixed cultures are less commonly reported and may be associated with chronic sinusitis.

In general, streptococci are common isolates in brain abscess and are reported in most series. A detailed study of streptococci associated with man reported *Streptococcus milleri* in 13 of 16 streptococcal brain abscesses (Parker and Ball 1976). Streptocci are commonly reported in more than 31 percent of brain abscesses – the actual figure may be higher than this as microaerophilic streptococci may be classified as anaerobes in some series. In some cases the reported figure is as high as 70 percent (De Louvois et al. 1977a; Ariza et al. 1986; Mathisen et al. 1985). The most frequently isolated are those of the *Streptococcus milleri* group (*anginosus*, *constellatus*, *intermedius*), which are well recognized to cause focal suppuration. An evaluation of infections caused by *Streptococcus milleri* found that 10 percent of them were brain abscesses (Molina et al. 1991).

Streptococcus pneumoniae is infrequently found in brain abscess despite being a common cause of meningitis. A review of 23 pneumococcal brain abscesses found that 50 percent of them had a contiguous focus such as sinusitis, otitis media or meningitis (Grigoriadis and Gold 1997).

Abscesses that follow trauma will show a range of bacteria related to the type of trauma. *Staphylococcus aureus* will be a common isolate after surgery, and is isolated in 10–15 percent of cases of postoperative brain abscess. Some of these will be methicillin resistant *Staphylococcus aureus* (MRSA) strains and are most likely to be in pure culture. *S. aureus* is also found in pure culture in intracerebral abscesses as a complication of endocarditis, and has recently been described in injecting drug users (Tunkel and Pradhan 2002).

Aerobic gram-negative bacilli are usually reported in mixed culture. Abscesses associated with chronic ear infections are most likely to yield these organisms, particularly *Proteus* spp. *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp. have also been recorded. *Klebsiella pneumoniae* has been associated with brain abscess in diabetics and produces a gas-forming appearance on X-ray imaging (Lu et al. 2002). Gram-negative bacilli have also been reported following neurosurgical procedures, accounting for 30 percent of cases in one report (Rau et al. 2002). *Pseudomonas aeruginosa* is rarely reported from otogenic abscesses despite its presence in the external ear canal of patients with chronic ear disease. It has been reported as a cause of meningitis and brain abscess in a premature baby (Shah et al. 1999). *Citrobacter freundii* has also been associated with neonatal brain abscess following meningitis (Curless 1980).

Listeria monocytogenes is a recognized cause of meningitis and brain stem encephalitis in the

immunosuppressed patient. Brain abscesses account for approximately 10 percent of cases (Eckburg et al. 2001) and are usually associated with concomitant meningitis and bacteremia in immunosuppressed patients.

Propionibacterium acnes is a true opportunist pathogen and is increasingly seen causing indolent infections in patients with prosthetic material. It is reported to cause post-operative brain abscesses which may be insidious in onset (Berenson and Bia 1989).

Focal intracranial infections with *Salmonella* spp. are rare; a review of the world literature identified only 43 cases, 11 of which were brain abscess mostly in adults (Rodriguez et al. 1986). Patients with HIV disease seem to be more at risk (Aliaga et al. 1997). *Salmonella typhi*, *typhimurium*, and *enteritidis* were the most common isolates. *S. typhi* has been reported to cause a brain abscess in a 2 month old (Hanel et al. 2000).

Nocardia spp. cause single or multiple abscesses and are associated with pulmonary disease or immunosuppression, or indeed as a primary infection in otherwise healthy individuals (Beaman and Beaman 1994). An increase in cases has been seen over the last decade in association with HIV disease. The causative organism is mostly *Nocardia asteroides* (Mamelak et al. 1994).

Rhodococcus equi is an unusual isolate from a brain abscess but was reported first in patients with HIV and recently in an immunocompetent patient (Corne et al. 2002).

Rare causes which have been reported in case reports are *Vibrio cholerae* non-0:1 (Ismail et al. 2001); *Mycoplasma hominis* and *Ureaplasma* (Rao et al. 2002); *Eikenella corrodens* (Asensi et al. 2002); *Capnocytophaga* (Engelhardt et al. 2002); and *Bacillus cereus* (Sakai et al. 2001).

Mycobacterium tuberculosis is a recognized cause of intracerebral lesions (tuberculomas) and the incidence is geographically determined. More cases are seen in Asia and the Far East than in Europe and North America. Acid-fast bacilli can be demonstrated in the pus from these lesions and should be actively looked for if cultures are negative and there are other risk factors for mycobacterial disease, such as immunosuppression and AIDS (Mathisen and Johnson 1997).

Clinical presentation

The clinical manifestations are caused by the presence of a space-occupying lesion in the brain, and the presentation may vary from indolent to fulminant. Symptoms may be nonspecific which can lead to delays in diagnosis. The most common symptom is headache, either hemicranial or generalized, and this may occur in up to 70 percent of patients (Table 3). Sudden worsening of the headache with associated meningism may indicate rupture of the abscess into the ventricle which carries a high mortality rate.

Table 3 *Common signs and symptoms of brain abscess*

Signs or symptoms	Frequency (%)
Headache	70–90
Focal neurology	>60
Fever	45–50
Triad of fever, headache, and focal neurology	<50
Seizures	25–35
Nausea and vomiting	25–50
Neck stiffness	25
Papilledema	25

Other common symptoms are fever, focal neurological signs, nausea, vomiting, and seizures which are usually generalized. If the abscess is near the meninges, neck stiffness may be present. The classic triad of fever, headache, and focal neurology is only seen in <50 percent of cases.

Other symptoms and signs vary with the location, size of the abscess, virulence of the infecting organisms, and the patient's immune status. Fever occurs in <50 percent of patients and the absence of fever should not exclude the diagnosis.

Patients with frontal lobe abscess are more likely to have mental status changes, speech disturbances or hemiparesis with unilateral motor signs. Those with a temporal lobe abscess may have headache, aphasia, and visual field defects. Cerebellar abscesses cause vomiting, ataxia, nystagmus, and dysmetria. Brain stem abscesses cause vomiting, hemiparesis, dysphagia, and facial weakness.

The symptoms caused by the contiguous focus of infection may predominate (for example, discharging ear). The duration of symptoms varies from a few days to as long as 6 weeks. About 75 percent of cases will have symptoms for 2 weeks (Wispelwey et al. 1997). In the immunocompromised patient the presentation may be occult because of reduced inflammatory response (Conti and Rubin 1988).

Diagnostic methods

The diagnosis of intracranial sepsis has been revolutionized by the introduction of CT and MRI scanning. These new techniques have rendered older more invasive diagnostic tests such as angiography and ventriculography virtually obsolete. Scanning methods also allow examination of the paranasal sinuses, mastoids, and middle ear.

The characteristic appearance of a brain abscess on a CT scan is that of a hypodense center with peripheral uniform ring enhancement following injection of contrast material, surrounded by a variable hypodense area of edema (Figure 2). MRI scanning is more sensitive particularly in the early stages and will detect

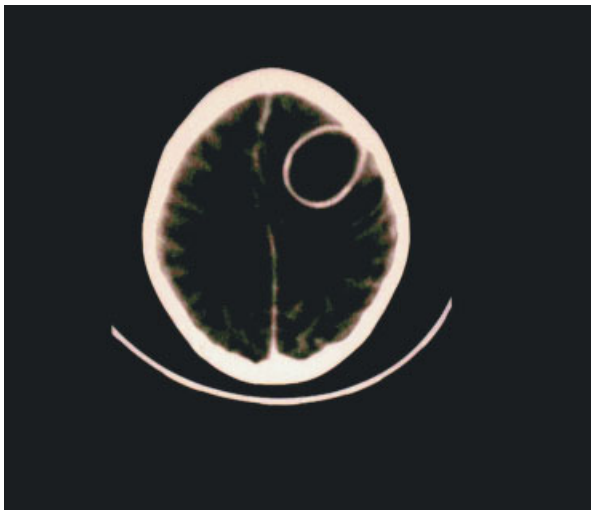

Figure 2 *Contrast enhanced CT scan showing ring enhancing frontal lobe lesion.*

abscesses in the early cerebritis stage (Figure 3). It is also better at defining brain stem abscesses. These forms of imaging are now the main diagnostic tool.

Diagnostic samples may be sent to microbiology; blood cultures will usually be negative. Lumbar puncture to obtain a sample of cerebrospinal fluid (CSF) is contraindicated as there is a significant risk of brain stem herniation (Chun et al. 1986), which outweighs any possible benefit of examining the CSF, which will show a negative or nonspecific result. The CSF may be positive if the abscess has ruptured into the ventricles or subarachnoid space.

Figure 3 *Gadolinium enhanced MRI scan showing temporal lobe abscess.*

There may be a peripheral leukocytosis, but 40 percent of patients will have a normal cell count. Other inflammatory indicators such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) may show elevation. The CRP may be more often raised in intracranial sepsis than in patients with neoplasm and may be useful in differentiating the diagnosis (Hirschberg and Bosnes 1987).

Samples of pus are readily sent for microbiology from surgery and are essential to define the infecting microorganisms, particularly in immunocompromised patients where a variety of bacteria, fungi, or parasites may be causing the infection.

Treatment

ANTIBIOTICS

The availability of antibiotics has undoubtedly contributed to the reduction in mortality seen with brain abscess. Prior to the discovery of antibiotics treatment was only surgical and usually led to death. In the early days of antibiotic use, large amounts of penicillin and streptomycin were instilled into abscess cavities and showed some promising results (Garfield 1969). The availability of more active agents in recent years has shown more improvements and now regimens can be tailored to cover the polymicrobial flora of brain abscesses.

When choosing an antibiotic to treat brain abscess, consideration has to be given to the penetration of the antibiotic into brain tissue. The cerebral capillary endothelial cells constitute the blood–brain barrier, which limits the penetration of numerous substances including antibiotics, into the brain. Inflammation as in meningitis disrupts the tight junctions and allows easier penetration of antibiotics, such as penicillin, into the brain. Other factors regulating antibiotic penetration into the brain include molecular size and structure, lipid solubility, degree of ionization at physiological pH, protein binding, and active transport mechanisms (Everett and Strausbaugh 1980). Antibiotic penetration into CSF has been extensively studied, but the blood–brain and the blood–CSF barriers are not identical and results may not be extrapolated (Gortvai et al. 1987). Therapeutic concerns about abscesses would be whether the results of CSF drug penetration would apply directly to brain abscess therapy, what would be the effect of the abscess environment on activity of antibiotics, and the possibility of negative drug interactions when multiple agents are administered. Certain antibiotics, for example penicillin and chloramphenicol, may be inactivated by abscess pus (Gortvai et al. 1987) and aminoglycosides are ineffective in the acid environment of an abscess. Chloramphenicol may antagonize the effects of penicillin and gentamicin as noted in experimental meningitis models (Tunkel and Scheld 1989). These are of course theoretical concerns

and few studies have addressed these issues in clinical practice.

The key question to ask is what is the concentration of antibiotic in the pus, and overall there have been only a few studies looking directly at this. The earliest study looked at brain tissue, CSF, and serum from 27 patients having a prefrontal lobotomy who had been given a dose of antibiotic preoperatively (Wellman et al. 1954). Tetracycline was detectable in the CSF and brain, but penicillin was not detected in either, perhaps reflected by the low dose that was given. Some other antibiotics were studied (Kramer et al. 1969) in patients having an intracranial neoplasm excised, they were given a bolus antibiotic dose of 2 g, and achieved the following brain:-blood levels: chloramphenicol 9:1, cephalothin 1:10, penicillin 1:23, ampicillin 1:56. On the basis of this study chloramphenicol has been used in the treatment of brain abscess for its excellent penetration into brain tissue; however, it lacks bactericidal activity and has the potential for serious side effects. Black and colleagues (Black et al. 1973) analyzed antibiotic concentrations in brain abscess pus from six patients. Chloramphenicol, methicillin, and penicillin were detectable after standard doses, but nafcillin was not. All the patients deteriorated clinically until surgical drainage was carried out; the cultures were still positive at the time of surgery. This highlighted the importance of surgery as part of the management. Another group analyzed pus from 32 patients (De Louvois et al. 1977b) for various antibiotics. Penicillin G was found to be present, but only if the dose exceeded 24 mega units per day. Incubating the pus for 1 h inactivated the penicillin by 90 percent in four of 22 samples (De Louvois and Hurley 1977). Fusidic acid was found to enter readily but cephaloridine, cloxacillin, and gentamicin showed only low levels. Metronidazole achieves high levels in pus (Ingham et al. 1977) and is widely used in combination to ensure bactericidal anaerobe activity. A single report looked at vancomycin levels in one case and found excellent concentrations (Levy et al. 1986). The first generation cephalosporins have not been recommended for treatment as they have poor CNS penetration, but the second and third generation agents have been shown to have very good CSF penetration and are widely used for treating meningitis. Of course the activity in brain pus cannot be predicted from that. Cefotaxime has been evaluated in brain pus (Sjolin et al. 1991) and it was found that cefotaxime and its active metabolite, desacetylcefotaxime, were present in the pus in concentrations above the minimum inhibitory concentrations (MIC) for the likely infecting organisms. Cefotaxime was evaluated in combination with metronidazole in 15 patients who also had surgery, and the outcomes were good (Sjolin et al. 1993). Ceftazidime, ceftriaxone, and ceftizoxime have all been used successfully in the treatment of small numbers of patients (Green et al. 1989; Donald and Ispahani 1988, 1990). Moxalactam has been shown to reach adequate concentrations in brain abscess pus and has been successful in treatment, but the toxicity of this agent precludes its use in treatment regimens (Yamamoto et al. 1993). Ampicillin/sulbactam was used in 11 patients with brain abscess with success and concentrations in the pus were variable, but adequate (Akova et al. 1993).

Imipenem-cilastatin, a carbapenem antibiotic, has been used successfully in the treatment of brain abscess (Asensi et al. 1996) and also in cerebral nocardiosis (Krone et al. 1989). The drug has a side effect of neurotoxicity so should be reserved for cases of resistant organisms. Meropenem, which is related to imipenem, does not have the same neurotoxic effects. Although limited evidence has been published for its efficacy in brain abscess, it has however been used successfully in treating meningitis. There is one report of successful use in a child with an *Enterobacter cloacae* abscess (Meis et al. 1995).

Cerebral nocardia has also been successfully treated with trimethoprim-sulphamethoxazole combined with surgery (Maderazo and Quintiliani 1974) and this combination may be used for Enterobacteriaceae depending on sensitivities.

Newer antibiotics, such as the quinolones, have not been studied in detail. There is evidence that they have good CSF penetration, and are highly active against the Enterobacteriaceae and Pseudomonads. There are inadequate data to support their use in brain abscess, but anecdotal evidence and case reports provide evidence of their clinical efficacy (Wessalowski et al. 1993). They should be used with some caution as they can lower seizure thresholds.

Undoubtedly some of the newer antimicrobial agents will be useful in the future as they offer additional options for treatment and possibly increased efficacy. There is a growing trend for nonoperative treatment of brain abscess and the new agents may have a part to play.

The antimicrobial regimens recommended for the treatment of intracerebral abscess are largely empiric and are based on the aforementioned studies (Table 4). No controlled trials have been undertaken;
the type of surgery performed also influences the outcomes. The predisposing condition and the site of the abscess is a guiding factor. The initial Gram stain on a pus sample is essential information for guiding empiric antibiotic therapy, which can be modified once culture results are available. Antibiotics should be started as soon as the diagnosis is made: there is no reason to wait for a pus sample before starting therapy, as cultures may still be positive despite antibiotic treatment.

Penicillin remains a mainstay of therapy because of its excellent activity against streptococci; the *Streptococcus milleri* group are commonly found in abscesses. It has a low incidence of side effects, and for many years was combined successfully with chloramphenicol. However, chloramphenicol is associated with side effects and is not

Table 4 *Suggested empiric antimicrobial therapy for brain abscess*

Predisposing condition	Antimicrobial regimen
Chronic ear disease	Third generation cephalosporin plus metronidazole
Sinusitis	Penicillin or third generation cephalosporin plus metronidazole
Dental infection	Penicillin or third generation cephalosporin plus metronidazole
Hematogenous spread	Penicillin or third generation cephalosporin plus metronidazole. Flucloxacillin or vancomycin if *S. aureus* suspected
Trauma or post surgery	Third generation cephalosporin plus flucloxacillin or vancomycin. Consider ceftazidime if *P. aeruginosa* suspected
Immunosuppression	Third generation cephalosporin or meropenem. Ampicillin or meropenem if *Listeria* is suspected
	Meropenem or trimethoprim/sulfamethoxazole if *Nocardia* is suspected

Based on Calfee and Wispelwey (2000) and Tunkel et al. (2000).

bactericidal so should not now be used as a first line agent. Metronidazole is added to give anaerobic cover, as it should be assumed that anaerobes would be present in most cases. The third generation cephalosporins are now accepted as empiric therapy, either cefotaxime or ceftriaxone, and in combination with metronidazole provide an adequate empiric therapy for most sinugenic, otogenic, and odontogenic abscesses (Donald 1990). Adequate coverage for enterobacteria found in otogenic abscesses is provided by the cephalosporins. For abscesses where *Staphylococcus aureus* is suspected, for example, postoperative, then an antistaphylococcal penicillin such as flucloxacillin should be used, in combination with fusidic acid or rifampicin. If MRSA is likely then vancomycin should be used, again in combination with rifampicin depending on local sensitivities.

Local instillation of antibiotics into the brain abscess cavity is not generally recommended as local irritation can occur which will increase the incidence of seizures. Rarely, the local route may be indicated in a difficult, poorly resolving abscess which remains culture positive despite appropriate antibiotics.

SURGERY

Surgical drainage is an important part of the management of these abscesses and is recommended for all abscesses of 2.5 cm or greater. As well as draining pus and relieving the effects of intracranial pressure, a pus sample will provide valuable microbiological information to guide therapy. The procedures commonly used are aspiration by burr hole or open drainage and excision by craniotomy. The technique used will depend on the location of the abscess, whether multiple abscesses are present, and on the clinical state of the patient. A recent technique of closed aspiration using CT guidance is increasingly being used instead of open craniotomy and stereotactic guidance can be employed for greater accuracy (Wispelwey et al. 1997). Follow up CT scans should be done to monitor the size of the abscess.

Sometimes antibiotic treatment alone is used without surgery (Boom and Tuazon 1985). This would be in certain categories of patients, which includes those at high risk for surgery, those with concomitant meningitis or ependymitis, those with hydrocephalus requiring a shunt, and those with inaccessible or multiple lesions (Rosenblum et al. 1980).

Guidance as to the duration of therapy is variable; no controlled trials have been done. Past recommendations have been to give parenteral treatment for 6–8 weeks provided that the infecting organisms are susceptible and that adequate surgical drainage is achieved. Recent studies suggest that 3–4 weeks of parenteral antibiotics may be adequate for those patients whose abscesses have been excised, with 4–6 weeks recommended for those whose abscesses have been aspirated. Those given antibiotics alone should be treated for a minimum of 4 weeks with parenteral antibiotics (Report 2000). The benefit of using oral antibiotics for follow-on treatment is unproven: in practice oral antibiotics based on sensitivity testing may be given for a further 4–6 weeks (Skoutelis et al. 2000). The serum C-reactive protein may be used to monitor resolution of the inflammation (Brown et al. 1994).

Outpatient parenteral antibiotic treatment (OPAT) is used increasingly for treating patients outside hospitals, thus reducing the costs and morbidity associated with inpatient stay. It has been reported to be successful in a carefully selected group of patients with central nervous system infections including 19 with brain abscesses (Tice et al. 1999).

SUBDURAL EMPYEMA AND INTRACRANIAL EPIDURAL ABSCESS

These two conditions will be considered together as they very often occur together in the patient. Subdural empyema is the second most common type of intracranial bacterial infection, followed by intracranial epidural abscess – it is difficult to establish the true incidence. The subdural space lies between the two outer layers of the meninges: the dura mater and the arachnoid mater (Figure 4). There is a large potential space for pus to

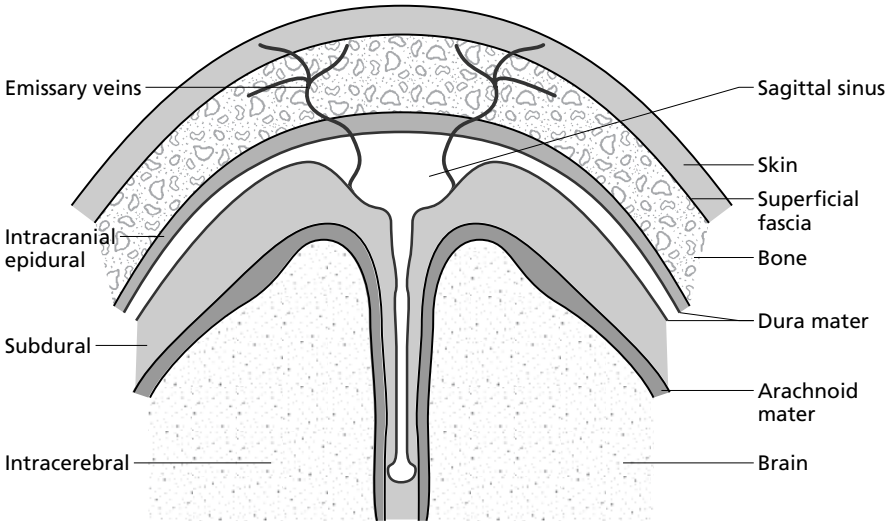

Figure 4 *Diagram of a cross-section through the skull showing the anatomy of the subdural space.*

spread through with only a few anatomical restrictions. Thus subdural empyemas behave as rapidly expanding space-occupying lesions. Overall, subdural empyemas account for 15–25 percent of localized bacterial infections of the CNS (Helfgott et al. 1997).

An epidural abscess represents infection between the outer layer of the dura mater and the overlying skull bone. There is little space there for pus to spread, so they are always very localized and usually associated with osteomyelitis. Subdural empyema is usually found in conjunction as the infection readily crosses the emissary veins. Virtually all cases follow sinusitis, craniotomy, or mastoiditis (Gallagher et al. 1998).

Epidemiology

Before the introduction of effective antimicrobial therapy the mortality from subdural empyema was uniformly 100 percent. After the introduction of penicillin the rate began to drop, and as with other forms of focal intracranial suppuration advances in diagnosis, surgical technique, and antibiotic therapy have brought the mortality rate down to 10–40 percent (Helfgott et al. 1997). Mortality is higher if the patient presents late or is comatose on admission, and in the elderly. Seizures may develop as a late complication (Dill et al. 1995).

Subdural empyema may occur at any age, but is most commonly seen in the second and third decades of life. Men are four times more commonly affected than women (Nathoo et al. 1999); it is seen in children (Smith and Hendrick 1983; Brook 1995). The most common predisposing factor, accounting for up to 60 percent of cases, is sinusitis, either frontal or ethmoidal. The rate may be higher in children. Ear infections account for a smaller number than with brain abscess, about 10–20 percent, but may be a more common predisposing factor in developing countries (Pathak et al. 1990). Hematogenous spread accounts for a small number of cases, around 5 percent, and this route may infect pre-existing subdural hematomas. Other cases have been reported following trauma, burns, and dental procedures. A series of 41 patients with postoperative subdural empyema showed that sinusitis accounted for only 29 percent of cases, 66 percent were postcraniotomy (Hlavin et al. 1994). Meningitis is an important predisposing factor in infants and subdural empyema may occur in 2 percent of infants with bacterial meningitis.

Uncomplicated intracranial epidural abscesses are, however, rare in children and have been reported from a wide age range with a median in the sixth decade. Recent case series suggest that a common predisposition for epidural abscess is surgery, up to 2 percent of craniotomies may be complicated by this infection (Hlavin et al. 1994).

Pathogenesis

Infection may spread directly or indirectly into the subdural space. Direct extension from the sinuses occurs by erosion of the posterior bony wall of the frontal sinus by infection, then further erosion of the dura mater to spread into the subdural space. It is thought that the most likely route is that of indirect spread by infection leading to thrombophlebitis of the emissary veins which connect the facial and dural venous systems. An epidural abscess always arises from infection of contiguous structures, such as sinuses and ear, and osteomyelitis is usually present. Infection from the ears occurs by the same mechanisms, either direct through the bone of the mastoid air cells, or indirect spread via the venous system (Bleck and Greenlee 2000a).

Bacteriology

Many different types of aerobic and anaerobic bacteria have been reported from epidural abscesses (Table 5); however, up to 30 percent may be negative on culture. Many of these patients will have had antibiotics prior to a sample of pus being taken. The types of bacteria grown will reflect the predisposing source. Streptococci are the most common isolates, being found in around 35 percent of cases, and are the most common isolate in children (Smith and Hendrick 1983). Most of these will belong to the *Streptococcus milleri* group. Sinugenic subdural empyemas most often grow streptococci, aerobic or anaerobic, often in pure culture. Staphylococci, in particular *Staphylococcus aureus*, are less commonly reported and account for 12–17 percent of cases. Most of these will be after surgery, trauma or related to hematogenous spread. *Staphylococcus aureus* is a frequent isolate from intracranial epidural abscess. This is due to the higher incidence of postoperative cases.

Skin flora such as *Propionibacterium acnes* have been reported in postoperative cases of subdural empyema (Critchley and Strachan 1996).

Aerobic gram-negative bacilli are less commonly reported, and usually in association with trauma and surgery (Hlavin et al. 1994). *Salmonella* spp. have been reported in neonates and infants (Mahapatra et al. 2002). Other unusual isolates are *Serratia marcescens* (Safani and Ehrensaft 1982) and *Pasteurella multocida* (Stern et al. 1981).

Subdural empyema following meningitis will reflect the causative organism of the meningitis, i.e. *Haemophilus influenzae*, *Streptococcus pneumoniae* or *Neisseria meningitidis* (Jacobson and Farmer 1981).

Polymicrobial infections are much less commonly reported compared to intracranial abscesses, but may be associated with surgery or trauma. As with other intracranial abscesses anaerobes play an important part and may be present either in pure culture or as part of a polymicrobial infection (Yoshikawa et al. 1975).

Mycobacterium tuberculosis is not often associated with subdural empyema despite it being a common cause of other CNS infections (Van Dellen et al. 1998).

Clinical features

In subdural empyema, fever and focal headache are prominent early features, the headache may then become generalized (Table 6). Focal neurological deficits may develop within 24–48 h with vomiting and signs of meningeal irritation. The symptoms can progress rapidly and focal fits can develop in 50 percent of patients. The presentation of localized epidural abscess may be more insidious and the initial presentation will be of the predisposing infection such as sinusitis.

Diagnostic methods

It is important to consider the diagnosis of subdural empyema in patients with sinusitis who go on to develop signs of meningeal irritation, for example, neck stiffness. The investigation of choice is gadolinium enhanced MRI scan which is more sensitive than contrast enhanced CT scan for this condition (Figure 5). Lumbar puncture should not be performed as it is dangerous and will not help in the diagnosis. Blood cultures may be positive in around 10 percent of cases,

Table 5 *Microbial cause and initial antibiotic therapy for cranial subdural empyema and epidural abscess*

Site of primary infection	Probable organism	Suggested initial therapy
Paranasal sinuses	Aerobic, microaerophilic, and anaerobic streptococci (especially *S. milleri* group); *Bacteroides fragilis* and other anaerobes; *Staphylococcus aureus*; *Haemophilus spp.*	Third generation cephalosporin plus metronidazole
Otitis media or mastoiditis	Aerobic, microaerophilic, and anaerobic streptococci (especially *S. milleri* group); *Bacteroides fragilis* and other anaerobes; *S. aureus*; Enterobacteriaceae	Third generation cephalosporin plus metronidazole
Cranial surgery or trauma	*S. aureus*; coagulase negative staphylococci, *Clostridium* spp.; Enterobacteriaceae; *Propionibacterium acnes*	Flucloxacillin or vancomycin plus third generation cephalosporin plus metronidazole
Dental sepsis	*Fusobacterium* sp.; *Actinomyces* sp.; aerobic and anaerobic streptococci	Metronidazole plus penicillin or third generation cephalosporin
Meningitis in infants	*Haemophilus influenzae*; *S. pneumoniae*; *Neisseria meningitidis*	Third generation cephalosporin
Meningitis in neonates	*Salmonella* spp; group B streptococci, Enterobacteriaceae	Third generation cephalosporin

particularly in children, and may be helpful in identifying the causative organism.

Treatment

The principles of antibiotic treatment have already been outlined, and it is necessary to choose an antibiotic which will penetrate the blood–brain barrier. The antibiotic choices for subdural and epidural empyema are similar to those for intracranial abscess (Table 5).

Early surgical treatment is essential to remove the pus and relieve the pressure on the brain (Nathoo et al. 1999).

The clinical symptoms, range of bacteria isolated, and management of intracranial epidural abscess mirrors that of subdural empyema. The mortality for uncomplicated intracranial epidural abscess is, however, lower than that for subdural empyema and a recent series showed a mortality rate of 18 percent (Hlavin et al. 1994). A good outcome depends on early diagnosis before irreversible neurological deficits are present.

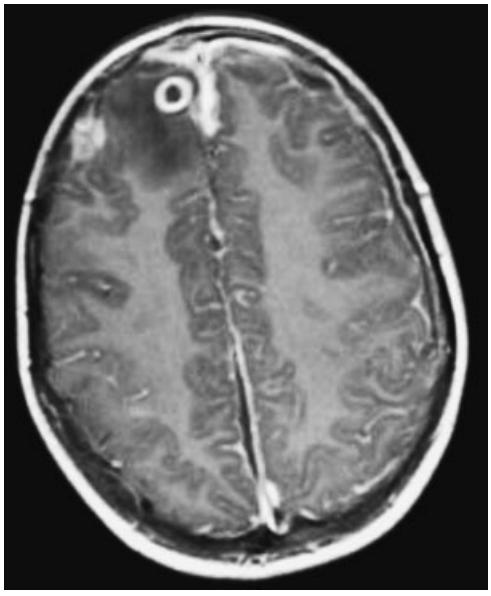

Figure 5 *Gadolinium enhanced MRI scan showing subdural empyema and frontal lobe abscess.*

SPINAL EPIDURAL ABSCESS

A spinal epidural abscess is a localized collection of pus in the paraspinal epidural space. This surrounds the spinal cord between the dura and the bone (Figure 6). This condition is a medical emergency because irreversible damage can be caused to the spinal cord by pressure of the abscess. In the preantibiotic era, these conditions were progressive and universally fatal, but with the advent of antibiotics and better diagnostic and surgical techniques these infections have a better outcome with mortality rates as low as 5 percent (Darouiche et al. 1992); although in some reports the mortality rate remains high at 18–31 percent (Hlavin et al. 1990). The higher mortality rates are thought to be in cases where the diagnosis was delayed; delays in diagnosis also lead to a worse outcome in terms of neurological sequelae.

Epidemiology

Spinal epidural abscess is an uncommon condition. Estimated incidence rates from case series range from 0.2 cases per 10 000 population in the mid 1970s (Baker et al. 1975) to 2.8 cases per 10 000 population more recently as observed in large tertiary care centers (Hlavin et al. 1990). The incidence is reported to be increasing; factors which may account for this are an increase in cases in injecting drug users; more patients with cancer who receive epidural analgesia, and more patients having spinal surgery or invasive diagnostic procedures.

There is a broad age range reported from 14-day-old infants (Rubin et al. 1993) to 78 year olds (Del Curling et al. 1990). It is most common in adults and the average age is now over 50 years of age, reflecting the increasing age of the at risk population. It is a condition which is increasingly seen in injecting drug users who tend to have an average age of 35 years (Koppel et al. 1988).

The male to female ratio has stayed consistent with a male predominance (Reihsaus et al. 2000).

Predisposing conditions

Spinal epidural abscess follows infection elsewhere in the body. Most cases reach the epidural space by the hematogenous route, either by direct seeding of the epidural space or by causing vertebral osteomyelitis which then extends into the epidural space. Infection may also spread from contiguous foci of infection, such as decubitus ulcers, retropharyngeal abscesses, and retroperitoneal infection. Increasingly, cases are seen following direct inoculation from surgery, from spinal procedures, such as epidural catheters for analgesia or

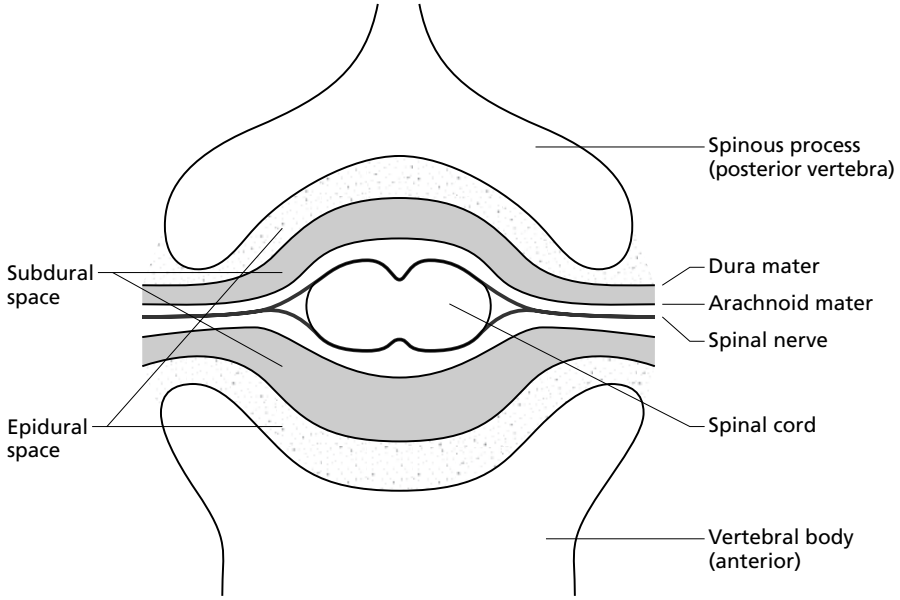

Figure 6 *Diagram showing the anatomy of the spine and the relationships of the epidural space.*

after spinal biopsy procedures (Bleck and Greenlee 2000a). Sometimes there is an underlying medical condition such as diabetes, degenerative joint disease, cirrhosis of the liver, or malignancy. Hematogenous seeding of the epidural space may occur in patients with endocarditis. In children, vertebral osteomyelitis is rare and most cases are associated with direct hematogenous spread.

The primary source is not apparent in 20–40 percent of cases (Gellin et al. 1997).

Pathogenesis

Spinal abscesses may be acute or chronic; chronic abscesses are more often associated with tuberculous osteomyelitis and epidural abscess.

The most common site for an abscess is posterior to the spinal cord; this occurs in 70 percent of cases. Anterior abscesses are more common in tuberculous infections and occur in the thoracic and lumbar regions. The abscess usually occupies about three to six vertebral segments, but rarely may extend more widely up and down the spinal column. Children are less likely to have adjacent vertebral osteomyelitis and usually have abscesses in the cervical or lumbar regions. The thoracic area is most common in adults.

The damage caused by the infection is often out of proportion to the size of the abscess. This may be due to several factors including thrombosis and thrombophlebitis of veins draining the spinal cord leading to edema and venous infarction; focal areas of vasculitis induced by the inflammatory mass; or bacterial exotoxin production particularly that due to *Staphylococcus aureus* (Gellin et al. 1997).

Bacteriology

A microbiological diagnosis is made from blood cultures, which may be positive in up to 90 percent of cases particularly if *S. aureus* is present, or by examination of pus drained at operation. Infections are rarely polymicrobial, only about 10 percent of cases having multiple isolates (Darouiche et al. 1992). *Staphylococcus aureus* is the most common isolate in all series accounting for up to 90 percent of cases; MRSA is also reported (Danner and Hartman 1987; Tang et al. 2002). Aerobic streptococci including *Streptococcus pneumoniae* (Turner et al. 1999) and *Streptococcus milleri* (Gelfand et al. 1991) are reported in up to 18 percent of series. The occurrence of aerobic gram-negative bacilli, including *Pseudomonas aeruginosa*, is on the increase both in postoperative cases and in injecting drug users; up to 37 percent of isolates may be gram-negative bacilli (Gellin et al. 1997). Coagulase-negative staphylococci are associated increasingly with postoperative cases. *Mycobacterium tuberculosis* is a well recognized cause of vertebral osteomyelitis and epidural abscess and is reported in most series.

The increase in infections seen in injecting drug users is represented in most series (Tunkel and Pradhan 2002) and may account for up to 40 percent of cases (Nussbaum et al. 1992).

Clinical features

The initial features may be subtle. There are four characteristic stages described (Gellin et al. 1997). The first symptom, with fever and malaise, is focal back pain. This is followed by nerve root pain; the next stage is

Table 7 *Bacterial isolates and suggested antibiotic therapy for spinal epidural abscess*

Bacteria	Frequency	Suggested antibiotics
S. aureus including MRSA	60–90%	Flucloxacillin or vancomycin plus rifampicin
Aerobic and anaerobic streptococci	18%	Benzylpenicillin plus metronidazole
Aerobic gram-negative bacilli	13%	Third generation cephalosporin or ceftazidime or quinolone
Polymicrobial	10%	Third generation cephalosporin plus metronidazole

spinal cord dysfunction, such as incontinence or sensory loss. The final stage is cord compression leading to paralysis. All this may happen over a short timescale; the progression of symptoms to nerve root pain can be over 3 to 4 days, then signs of cord compression over the next 4 to 5 days. At this stage the neurological effects are usually reversible but urgent surgical intervention is still needed as paralysis can develop rapidly. Acute infections, usually due to hematogenous spread, will progress rapidly in under 2 weeks with prominent signs of local infection, whereas abscesses arising from vertebral osteomyelitis will have a longer duration of back pain lasting more than 2 weeks before neurological symptoms appear. Back pain is a very common symptom, so epidural infection is often not considered as a diagnosis until neurological symptoms appear.

Diagnosis

Routine tests will show that the inflammatory markers, such as ESR and CRP, will be raised, as will the peripheral blood leukocyte count. Cerebrospinal fluid examination is sometimes performed and will show evidence of parameningeal inflammation, in other words raised white cell count and protein. The CSF cultures should be negative unless the abscess was directly sampled in which case the white cell count would be very high and the cultures will yield the causative organism.

Radiological diagnosis is made by MRI scanning using gadolinium enhanced scans which are very specific for this type of abscess.

Management

Surgical drainage to relieve pressure on the spinal cord is essential and is an emergency procedure. Antibiotics should be started as soon as possible to cover the common pathogen, *S. aureus*, with antipseudomonal cover added in postoperative cases and injecting drug users (Table 7). The spinal epidural space is outside the blood–brain barrier which will make antibiotic choice easier. Recommended duration of therapy is intravenous antibiotics for 3 to 4 weeks, then oral agents for a further 2 to 3 months if vertebral osteomyelitis is present. Some studies have recommended a shorter duration of therapy (Del Curling et al. 1990).

Some reports suggest that nonsurgical management may be successful (Wheeler et al. 1992), but the patients were carefully selected and the true success of this is difficult to ascertain. Some patients in another series showed progression of symptoms while on antibiotics alone (Hlavin et al. 1990).

It is well reported that a delay in diagnosis leads to a worse outcome. The preoperative status of the patient is a good predictor of outcome; those that are paralyzed before surgery do worse (Mackenzie et al. 1998).

Bacterial infections of the eye

SUSAN E. SHARP AND MICHAEL R. DRIKS

Introduction	1	Bacterial keratitis	4
Normal flora and common pathogenic bacteria of the eye	1	Bacterial endophthalmitis	5
Bacterial conjunctivitis	1	Conclusions	7
		References	7

INTRODUCTION

This chapter will focus on bacterial infections of the eye, specifically those associated with conjunctivitis, keratitis, and endophthalmitis. Within each of these infections, the areas of predisposing factors, clinical manifestations, infecting agents, diagnosis, and treatment will be reviewed.

Infections of the eye can be exogenously acquired, contiguous (from infections of the face, eyelids, etc.), or from hematogenous spread (O'Brien 2000). One or more of these routes can be associated with each of the above conditions.

NORMAL FLORA AND COMMON PATHOGENIC BACTERIA OF THE EYE

The bacterial organisms most commonly associated with 'normal flora' and the 'common pathogenic' bacteria of the eye are indicated in Table 1 (Sharp 1999; O'Brien 2000).

BACTERIAL CONJUNCTIVITIS

Predisposing factors

Conjunctivitis is defined as inflammation of the conjunctiva, usually caused by infections, allergens, or irritative substances. Predisposition to bacterial conjunctivitis primarily involves contact exposure to airborne fomites, upper respiratory infections, skin flora on hands, or genital secretions (O'Brien 2000). A patient's age is an important determinant of the likely infecting organism. In children, bacterial conjunctivitis is more common than viral, whereas in adults, the opposite is true (Wishart et al. 1984; Fitch et al. 1989; Woodland et al. 1992). The clinical setting can also determine the microbiology of bacterial conjunctivitis. Institutional outbreaks have been described, presumably due to contact transmission between residents, patients, and medical personnel (King et al. 1988; Schwartz et al. 1988). Community outbreaks of *Haemophilus influenzae* biogroup *aegyptius* occur in children.

Clinical manifestations

All forms of conjunctivitis may be characterized by irritation, itching, foreign body sensation, tearing, and discharge. Bacterial conjunctivitis can be distinguished from other forms by the presence of mucopurulent drainage and a papillary reaction, characterized by many small bumps on the tarsal conjunctiva, creating a velvety appearance (Chung and Cohen 2000). In contrast to viral causes, bacterial conjunctivitis is typically unilateral. In severe cases, there is often significant lid edema with copious purulent drainage, marked conjunctival erythema, chemosis, membrane formation, and associated keratitis (O'Brien 2000). *Neisseria* conjunctival infections cause especially severe inflammation (Valenton and Abendanior 1973; Barquet et al. 1990). Streptococci and *Corynebacterium diphtheriae* are notable for causing membrane formation (Boralkar 1989). Nonpyogenic bacterial organisms, including

Table 1 *Bacterial organisms most commonly associated with 'normal flora' and the 'common pathogenic' bacteria of the eye*

Normal flora	Most common pathogens
Aerobic bacteria	Aerobic bacteria
Corynebacterium	*Streptococcus pneumoniae*
Staphylococcus species	*Staphylococcus aureus*
Micrococcus	*Staphylococcus*, coagulase-negative
Nonpathogenic *Neisseria* species	*Streptococcus* species
Aerococcus	*Pseudomonas aeruginosa* and other gram-negative bacilli
	Haemophilus influenzae
	Moraxella catarrhalis
	Neisseria gonorrhoeae
	Neisseria cinerea
	Bacillus species
	Chlamydia trachomatis
Anaerobic bacteria	Anaerobic bacteria
Propionibacterium	*Propionibacterium*
Clostridium	*Peptostreptococcus*
Peptostreptococcus	

Mycobacterium tuberculosis, *Francisella tularensis*, *Treponema pallidum*, and *Bartonella henselae* can cause an atypical conjunctivitis with unilateral nodules that ulcerate and ipsilateral preauricular lymphadenopathy.

Chlamydial conjunctivitis deserves special mention. Trachoma refers to conjunctival and limbic scarring leading to trichiasis and corneal opacification in recurrent or chronic *Chlamydia trachomatis* infection (Bobo et al. 1997). Trachoma is among the leading causes of blindness in the world. Inclusion conjunctivitis is an acute infection in adults, most often transmitted by contact with genital secretions. In a neonate infected during the birthing process, the disease is grouped together with gonococcal conjunctivitis and referred to as opthalmia neonatorum. As of the 1970s, the incidence of chlamydial conjunctivitis in the newborn was increasing, involving 2.8 percent of all births in one clinic and 35 percent of infants born to mothers with known chlamydial cervicitis (Schachter et al. 1979). The usual incubation period is 5–12 days from birth (Chandler et al. 1977). In infants born to infected mothers, 22–44 percent develop neonatal conjunctivitis (Harrison and Alexander 1990).

Infectingagents

In the healthy and nonimmunocompromised population, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *H. influenzae* are the most common causes of acute bacterial conjunctivitis. However, differences in causative organisms are seen based on the age of the patient.

In the newborn, acute conjunctivitis can be caused by *C. trachomatis*, *Neisseria gonorrhoeae*, *Neiserria cinerea*, or *Pseudomonas aeruginosa*, although *C. trachomatis* and *N. gonorrhoeae* are the most frequently encountered organisms in this population (de Toledo and Chandler 1992; Ratelle et al. 1997). Studies have shown *H. influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis* to be the bacterial agents most often associated with acute conjunctivitis in children (Weiss et al. 1993; Gigliotti et al. 1981; Wald et al. 2001). *H. influenzae* has been reported to be the most prevalent isolated pathogen, accounting for between 54 and 74 percent of infections in children (Gigliotti et al. 1981; Wald 1997; Wald et al. 2001). Ocular *H. influenzae* isolates also appear to be mostly serologically nontypable strains, probably as a result of the widespread use of the *H. influenzae* b vaccine (Alrawi et al. 2002; Robinson et al. 2001). Conjunctivitis in young children may also be caused by *N. cinerea*, *S. aureus*, or *P. aeruginosa* (Trottier et al. 1991; Weiss et al. 1993; Iroha et al. 1998; Shah and Gallagher 1998). In addition, the *Streptococcus* viridans group have been shown to be associated with conjunctivitis in patients aged less than 1 year (Seal et al. 1982).

In adults, the most common causes of bacterial conjunctivitis are *S. pneumoniae*, *S. aureus*, and coagulase-negative staphylococci, while in sexually active teenagers and adults, *C. trachomatis* and *N. gonorrhoeae* can also be found (Seal et al. 1982; O'Brien 2000). Additional bacteria such as those listed at the beginning of this chapter can also be found to cause conjunctivitis in a variety of community and nosocomial settings. For example, hospital- and institutionally acquired cases of conjunctivitis have been associated with infections caused by *Serratia marcescens*, *S. pneumoniae*, *P. aeruginosa*, and *Moraxella* spp. (van Ogtrop et al. 1997; King et al. 1988; Schwartz et al. 1988). Mycobacterial species, especially *M. tuberculosis*, have been shown to be an etiologic agent of atypical conjunctivitis and may be associated with ulcerations of the eye.

Organisms thought to be nonpathogenic can occasionally cause conjunctivitis. However, those bacteria normally considered skin flora may be cultured from diseased eyes without causing infection. For example, 40 percent of specimens in one study were associated with recovery of *S. epidermidis* or mixed skin flora, which also occurred in cultures of normal eyes (Seal et al. 1982). In another study of children, staphylococci, corynebacteria, and alpha-hemolytic streptococci were the predominant organisms recovered from the eyelids of uninfected control subjects (Weiss et al. 1993). In addition, a study by Gigliotti and colleagues found that *S. aureus* was as commonly isolated from normal eyes as from diseased eyes in children (Gigliotti et al. 1981). Thus, care must be taken when interpreting the results of bacterial cultures.

Diagnosis

The value of laboratory diagnostic procedures in mild conjunctivitis is not well established and is therefore not done routinely. Cases of mild conjunctivitis are often treated without the knowledge of bacterial culture information. In severe conjunctivitis, culture of the superior and inferior tarsal conjunctiva is recommended. In all cases of ophthalmia neonatorum, smears and cultures for bacteria, including *Chlamydia*, should be performed.

If culture diagnosis of bacterial conjunctivitis is desired, it can be attempted by performing conjunctiva cultures. Samples of both eyes should be taken with separate swabs that have been premoistened with sterile saline. For routine bacteriology collections, swabs that are used for normal bacteriology specimen collection should be used. If cultures for *Chlamydia* are being collected, cotton swabs should not be used, but dacron or calcium alginate swabs would be acceptable. Topical ointments and analgesics should be avoided prior to collection. Samples are collected by rolling the swabs over each conjunctiva. They should be directly inoculated on to blood agar and chocolate agar plates (warmed to room temperature prior to inoculation) or added to transport media for travel to, and inoculation in, the laboratory. After inoculation, the swabs are rolled across two separate slides for staining purposes. Plates inoculated at the bedside should be transported at room temperature to the laboratory as soon as possible, preferably within 15 min, or stored for up to 24 h at room temperature prior to delivery. If swabs are collected and not directly inoculated at the bedside, they should be placed back into the swab device sleeve, transported at room temperature, and delivered to the laboratory immediately and no longer than 2 h after collection. If samples are being collected for *Chlamydia* culture, appropriate *Chlamydia* transport media should be utilized for delivery of the specimens to the laboratory, again within 2 h of collection. In addition, molecular testing for the presence of *Chlamydia* can be performed if the sample is collected in specimen collection/transfer devices specific for this purpose. Swab samples are normally not appropriate for mycobacterial stain or culture. If *M. tuberculosis* conjunctivitis is suspected, ulcer/lesion scrapings can be collected for appropriate stains and cultures.

As stated earlier, if possible both conjunctiva should be sampled, even if one seems to be uninfected. This will allow the determination of the normal flora of the uninfected eye. This can be used for comparison with the organisms cultured from the infected eye and assist in the determination of possible pathogens. Anaerobic cultures are not performed in cases of conjunctivitis, as the causative bacterial pathogens are aerobic in nature. An exception might exist with *Peptostreptococcus*, an anaerobic gram-positive cocci; however, this is not a frequent cause of conjunctivitis.

The Gram stain can assist in the determination of the causative agent(s) of conjunctivitis, especially if only the infected conjunctiva is sampled. In acute bacterial conjunctivitis, specimens show large numbers of neutrophils, and bacteria may be seen inside or outside of these cells. With chronic conjunctivitis there are more lymphocytes and large mononuclear cells seen in the Gram stain as compared with neutrophils. Organisms seen on the Gram stain are more likely to be involved in the infective process and can be used to help interpret the bacterial culture information. Gram stains of conjunctival scrapings have been shown to provide a rapid means of predicting the causative agent in 90 percent of cases of bacterial conjunctivitis (Weiss et al. 1993).

Treatment

Mild bacterial conjunctivitis is often self-limiting, requiring no treatment. Multiple topical antibiotics, including aminoglycosides for Gram-negative organisms, eythromycin, bacitracin, polymyxin/trimethoprim, or neomycin/polymyxin for Gram-positive organisms, are available in ophthalmic preparations, given every 2–4 h for 7–10 days. Empiric therapy for children should focus on *H. influenzae*, *S. pneumoniae*, and *S. aureus*. Fluoroquinolone solutions offer broad-spectrum activity but have been no more effective than aminoglycosides. Gonococcal conjunctivitis requires parenteral treatment, usually with a single 125-mg dose of intramuscular ceftriaxone. Adult inclusion conjunctivitis and trachoma are treated systemically with doxycycline or macrolide antibiotics. Neonatal chlamydial conjunctivitis is treated with erythromycin. Prophylaxis of both gonococcal and chlamydial opthalmia neonatorum is best achieved with topical erythromycin (O'Brien 2000).

BACTERIAL KERATITIS

Predisposing factors

Keratitis is defined as inflammation of the cornea, produced by infectious and noninfectious causes. Microbial keratitis is a common, potentially sight-threatening infection. Bacterial keratitis accounts for 65–90 percent of all corneal infections (Jones 1981; Asbell and Stenson 1982; Liesegang and Forster 1980). Direct penetration of intact corneal epithelium occurs only by organisms with particular virulence factors. Most organisms gain access via corneal epithelial defects created by mechanical, thermal, or chemical injury or by epithelial erosion secondary to underlying ocular conditions (O'Brien 2000).

Various forms of external trauma, including obvious or subtle injury, contact lenses, trichiasis, entropion, and abnormal lid margins, predispose to infection. Radial keratotomy, now infrequently performed, is associated with infection in 0.25–0.7 percent of cases (Jain and Azar 1996). Infectious complications of photoreactive keratectomy using the excimer laser are rare (Lin and Maloney 1999).

Corneal surface defects may also result from severe dry eyes, exposure, bullous keratopathy, or neurogenic corneal anesthesia. Comatose patients with chemosis that prevents lid occlusion are prone to bacterial keratitis (Parkin et al. 1997). Underlying leprosy or trachoma with lagophthalmos or trichiasis are also at risk.

Clinical manifestations

There are no clinical symptoms or signs that reliably distinguish microbial keratitis from noninfectious inflammatory conditions. Due to the rich nervous innervation of the cornea, the most common complaint is pain. Unlike conjunctivitis, keratitis is usually accompanied by a variable decrease in vision. Examination of the patient is greatly facilitated by use of topical anesthesia. The cornea is assessed for epithelial ulceration and the presence and location of stromal suppuration. Again, unlike conjunctivitis, discharge is uncommon in keratitis. Reflex tearing, photophobia, and blepharospasm are common. Loss of corneal transparency and epithelial defects are best observed with a cobalt blue light after instillation of fluorescein. Neovascularization of the cornea may be seen in severe cases. Slit-lamp examination may reveal associated intraocular inflammation with flare and cells in the anterior chamber and hypopyon formation (O'Brien 2000).

Infecting agents

Both gram-positive and gram-negative bacteria can be associated with infective keratitis, and many organisms can cause keratitis when introduced by trauma or ocular abnormality. The most prevalent causative organisms include *Staphylococcus* spp., *Streptococcus* spp., *Pseudomonas* spp., and members of the Enterobacteriaceae (O'Brien 2000). Several studies have shown *P. aeruginosa* to be the dominant bacterial pathogen causing bacterial keratitis (Lam et al. 2002; Boonpasart et al. 2002; Martins et al. 2002; Sun et al. 2002), whereas others have found the gram-positive bacteria (staphylococci, *S. pneumoniae*, and other streptococci) to be the most frequent agents of bacterial keratitis (Schaefer et al. 2001; Sun et al. 2002; O'Brien 2000). Other infectious agents found to be associated with bacterial keratitis include *Moraxella* spp., *Serratia marcescens*, *Citrobacter* spp., *Enterobacter* spp., *Proteus* spp., *Morganella morganii*, *Bacillus cereus* (and other *Bacillus* spp.), *Corynebacterium* spp., *N. gonorrhoeae*, *Alcaligenes xylosoxidans*, *Acinetobacter* spp., *H. influenzae*, and *C. trachomatis* (Schaefer et al. 2001; Pinna et al. 2001; O'Brien 2000).

P. aeruginosa is a frequent cause of bacterial keratitis in contact-lens wearers and can cause a quick suppurative course due to the production of proteolytic enzymes that damage the eye (O'Brien 2000). *Streptococcus pyogenes*, also a common cause of bacterial keratitis in adults, may induce a severe inflammatory response due to the production of exotoxins (Bachman and Gabriel 2002). *B. cereus* is recognized as a primary pathogen of ocular infections and is commonly seen in infections associated with post-tramatic events (Tauzon 2000). Extremely serious and virulent ocular infections with this organism can be seen following a foreign body injury (O'Brien 2000).

Staphylococci that normally colonize other parts of the body can occasionally reach the eye and cause corneal infection. *N. gonorrhoeae* may cause keratitis resulting from an inappropriately treated conjunctivitis. Polymicrobic infections can be seen in association with 'bandage' contact lenses in diseased corneas, often associated with a mixture of bacterial and fungal organisms (O'Brien 2000). Several mycobacterial species have also been associated with chronic ulcerative keratitis, including, most commonly, *M. fortuitum* and *M. chelonae* and, much less commonly, *M. gordonae*, *M. avium complex*, and *M. tuberculosis*.

Diagnosis

Superficial keratectomy or corneal biopsy specimens may be necessary for difficult to diagnose nonsuppurative cases. For bacterial culture it is recommended that samples of both the conjunctiva and cornea be collected. Swabs of the conjunctiva should be collected prior to anesthetic applications, whereas corneal scrapings can be obtained afterward. Conjunctiva swab specimens should be collected as described earlier for

conjunctivitis. For routine bacteriology collections, swabs that are used for normal bacteriology specimen collection should be used. If cultures for *Chlamydia* are being collected, cotton swabs should not be used, but dacron or calcium alginate swabs would be acceptable. Again, if possible, both conjunctiva should be sampled, even if one seems to be uninfected to allow the determination of normal flora in the uninfected eye and possible pathogens in the affected eye. After collection of the conjunctiva swabs, instillation of two drops of local anesthetic should be administered. Using a sterile spatula, ulcers or lesions from the cornea are scraped and some of the scrapings are inoculated directly on to culture media (multiple samples from areas of suppurations should be obtained for each stain and medium). Direct culture inoculation should be performed on to brain–heart infusion agar supplemented with 10 percent sheep blood and chocolate agar. All media should be warmed to room temperature prior to inoculation. Anaerobic media is not routinely necessary as the majority of organisms associated with keratitis are aerobic in nature. The remaining material should be applied to two clean glass slides for staining. Inoculated specimens should be held at room temperature and transported to the laboratory within 15 min. If this is not possible, the inoculated specimens should be held at room temperature for not more than 24 h prior to transport to the laboratory. The majority of bacteria that cause keratitis will grow on standard media within 12–48 h.

The sensitivity and specificity of the Gram stain for the diagnosis of keratitis was determined in a study that examined corneal scrapings (Sharma et al. 2002). In this study, the sensitivity of the Gram stain in the detection of bacteria was 36.0 percent in early keratitis and 40.9 percent in advanced keratitis cases. However, the specificity was higher in both groups (84.9 and 87.1 percent, respectively), while predictive values were poor. This study determined that the Gram stain had limited value in determining therapeutic options for bacterial keratitis. However, it is still held that the diagnostic laboratory evaluation of corneal scrapings (including Gram stain and culture) is imperative if there is suspicion of microbial keratitis (O'Brien 2000).

Special methods are necessary for the detection of *C. trachomatis* or the mycobacterial species. Specimens can be inoculated into cell culture or tested by molecular detection techniques for *Chlamydia* detection. If samples are being collected for *Chlamydia* culture, appropriate *Chlamydia* transport media should be utilized for delivery of the specimens to the laboratory, within 2 h of collection. In addition, molecular testing for the presence of *Chlamydia* can be performed if the sample is collected in specimen collection/transfer devices specific for this purpose. For the detection of mycobacterial infections, routine acid-fast bacilli growth media/systems should be utilized.

Treatment

Bacterial keratitis is potentially sight-threatening and demands prompt attention. Corneal perforation with resulting endophthalmitis and eye loss can occur rapidly. Topical antibiotics remain the mainstay of treatment, but the potential for rapid deterioration and the need for high-frequency dosing often requires hospitalization with trained nursing personnel. Several routes of topical administration include drops, ointments, continuous lavage, antibiotic-soaked corneal shields, therapeutic soft contact lenses, and iontophoresis. Subconjunctival injection and parenteral routes are also utilized. Empiric antibiotics are usually begun pending return of diagnostic information. The antimicrobial agent selected should have bactericidal activity against common gram-positive and gram-negative corneal pathogens. A common initial choice includes a topical first-generation cephalosporin (e.g. cefazolin) and an aminoglycoside (e.g. gentamicin, tobramycin, or amikacin). Fluoroquinolone ophthalmic solutions are available for broad-spectrum coverage. Various penicillin, cephalosporin, vancomycin, aminoglycoside, and fluoroquinolone preparations are commercially available or can be formulated and fortified by the pharmacist for directed therapy once a microbiologic etiology is established (Forster 1998). The utility of susceptibility testing is unclear, due to the high local antibiotic concentrations afforded by topical therapy. Response to treatment is based on serial slit-lamp examinations. Decreasing frequency of antibiotic administration and conversion from fortified to commercial strength drops can usually occur within a few days.

BACTERIAL ENDOPHTHALMITIS

Predisposing factors

Endophthalmitis is an inflammatory process involving the deep structures of the eye. Bacteria are the most common cause of infectious endophthalmitis (O'Brien 2000). By far the most common predisposing factor for bacterial endophthalmitis is antecedent eye surgery. The incidence of postoperative endophthalmitis is low (<0.9 percent), but the high frequency of cataract extraction, glaucoma surgery, vitrectomy, and keratoplasty make it an important problem (Aaberg et al. 1998). As for keratitis, radial keratotomy and laser keratectomy are uncommonly complicated by endophthalmitis. Penetrating nonsurgical trauma is another significant presdisposing event, with endophthalmitis developing in 4.2 percent of cases (Duch-Samper et al. 1997). The presence of a distant focus of infection may predispose to endogenous bacterial endophthalmitis, secondary to hematogenous seeding. Cases associated with infection at virtually any site have been described, prominently

including meningitis, respiratory tract infection, abdominal infection, skin and soft-tissue infection, and endocarditis (Barnard et al. 1997). Occasionally, presumed hematogenous endophthalmitis occurs in a previously healthy patient with no apparent focus (Piczenik et al. 1997).

Clinical manifestations

Bacterial endophthalmitis typically develops suddenly and progresses rapidly. Symptoms and signs of ocular inflammation usually manifest within one to several days after surgical or nonsurgical trauma. Patients complain of pain and progressive blurring of vision. Examination reveals intense conjunctival hyperemia, chemosis, lid and corneal edema, hypopyon, and decreased visual acuity. Ophthalmoscopic or slit-lamp examination reveals anterior chamber and vitreous inflammatory cell reaction. Sudden onset of endophthalmitis in an unoperated, nontraumatized eye suggests hematogenous spread. The clinical picture of endogenous endophthalmitis is similar to postoperative cases, except for more prominent involvement of the posterior segment of the eye. These cases normally occur in systemically ill and/or immunocompromised patients (O'Brien 2000). Delayed-onset endophthalmitis can follow cataract extraction with intraocular lens implantation. These patients have a chronic course with low-grade inflammation (Fox et al. 1991; Sawusch et al. 1989).

Diagnosis

Once bacterial endophthalmitis is clinically suspected, prompt diagnostic aspirates should be obtained for thorough microbiologic investigation. Vitreous fluid has the highest yield for microbial pathogens and should be collected for the diagnosis of endophthalmitis along with aqueous aspiration. Microbiological studies should include a Gram stain and appropriate culture media for aerobic and anaerobic organisms. In one study, 78 of 140 specimens (56 percent) collected by vitreous and aqueous paracentesis were positive for a bacterial agent, with the vitreous having the higher yield as compared with the aqueous culture (O'Brien 2000). In another study that cultured vitreous fluid from over 400 patients with endophthalmitis, the overall yields of bacterial organisms recovered from solid media and broth culture were similar. This study also found that a positive Gram stain was highly predictive of a positive culture from the eye; however, a negative Gram stain had little predictive value for the culture result (Braza et al. 1997). Although culture results have little relevance on initial therapy choices, modifications of therapy can be directed by the results of bacterial culture and antimicrobial susceptibility testing. As stated previously, media for both aerobic and anaerobic bacteria should be included in the culture of these specimens; however, the use of broth cultures is not routinely necessary (Braza et al. 1997). The usual pathogens causing endophthalmitis should grow in 24–48 h, but cultures for anaerobic organisms may need to be held for up to 5–7 days. For suspected cases of mycobacterial infection, acid-fast stains and appropriate cultures should be performed.

Polymerase chain reaction (PCR) technology has been studied by several investigators for the diagnosis of bacterial endophthalmitis. Vitreous fluid and aqueous humor have both been shown to be reliable samples for use in PCR followed by sequencing procedures to detect the presence of bacterial organisms, especially in smear- and culture-negative specimens (Therese et al. 1998; Lohmann et al. 1998; Lohmann et al. 1997; Okhravi et al. 2000; Knox et al. 1999). A case of culture-proven *Listeria monocytogenes* endophthalmitis was identified more than 2 days sooner using PCR followed by direct sequencing protocols as compared with conventional culture (Lohmann et al. 1998). PCR was shown to be helpful in identifying *Propionibacterium acnes* in nine of 17 eubacterial genome-positive specimens that were smear- and culture-negative for bacterial organisms (Therese et al. 1998). The study by Lohmann and colleagues tested aqueous humor or vitreous in cases of endophthalmitis (21 eyes) and identified the causative organisms as *P. acnes*, *Staphylococcus epidermidis*, or *Actinomyces israelli* by PCR and comparing the determined sequences with all GenBank entries (Lohmann et al. 2000). The study by Okhravi and colleagues identified *Escherichia coli*, coagulase-negative staphylococci, *B. cereus*, *Pseudomonas* spp., *Comomonas* spp., *Proteus* spp., *Methylobacterium* spp., *Aeromonas* spp., and *Streptococcus faecalis* through detecting bacterial DNA by PCR and identifying sequences by restriction fragment length polymorphism and/or sequencing techniques (Okhravi et al. 2000). In addition, PCR techniques are a useful adjunct to diagnostic techniques, as unlike conventional culture, results are not affected by previously administered antibiotics (Lohmann et al. 2000). Caution must be taken when using PCR or other nucleic amplification techniques to detect 'causative' organisms, especially from nonsterile specimens such as eye collections. Identification of a certain genomic sequence proves that the specimen harbors this piece of nucleic acid (if not contaminated); however, it does not prove that the organism caused the patient's disease or that the organism is viable. Organisms determined to be present in clinical samples can be consistent with infection, colonization, or contamination, thus the results of molecular diagnostic techniques, as well as conventional bacterial culture, must be interpreted with caution. To date, these techniques are expensive and not part of the routine diagnostic microbiology laboratory. It is unclear at this time whether resources will be utilized for the development of PCR and sequencing commercial diagnostic kits for ophthalmic pathogens (Van Gelder 2001).

Treatment

Acute bacterial endophthalmitis is an ophthalmologic emergency, requiring early recognition and immediate and aggressive therapy. Traditional treatment options have included mechanical debridement via vitrectomy, intravitreal, subconjunctival, topical, and/or systemic antibiotics, and steroids by various routes. The Endophthalmitis Vitrectomy Study (Endophthalmitis Vitrectomy Study Group 1995) demonstrated that systemic antibiotics, such as ceftazidime and amikacin, did not improve visual outcome and that early vitrectomy benefited patients with light-perception vision or less on presentation. Patients with better than light perception (hand motions or better) fared equally well with vitreous tap and intravitreal antibiotics, with 50 percent achieving 20/40 or better vision, 75 percent with 20/100 or better, and only 12 percent with severe vision loss (5/200 or worse). Empiric intravitreal antibiotics are aimed at both gram-positive pathogens, including methicillin-resistant staphylococci, and gram-negative pathogens, including *Pseudomonas* spp. Vancomycin and an aminoglycoside is a common therapeutic combination. Amikacin is often chosen due to its possibly decreased retinal toxicity as compared with the other aminoglycosides. Similarly, concern for retinal toxicity has led to a trend toward ceftazidime use as a replacement for the aminoglycosides. Clindamycin is often included in nonsurgical post-traumatic cases because of the risk for *B. cereus* endophthalmitis. Adjunctive subconjunctival and topical antibiotics are often utilized, but their contribution beyond intravitreal antibiotics is unknown. Steroids are commonly added to hypothetically reduce destruction secondary to intraocular inflammation, but their efficacy is not well established. In delayed-onset chronic *P. acnes* endophthalmitis, surgical removal of intraocular lens implants may be necessary to remove sequestered organisms.

Prophylactic antibiotics and antiseptics before, during, and after surgery are widely utilized, but their efficacy is unproven. The low incidence of postoperative bacterial endophthalmitis makes demonstration of efficacy difficult. Povidone–iodine appears to be effective in reducing rates of these infections (Speaker and Menikoff 1991).

CONCLUSIONS

The eye is an anatomically and functionally complex structure, with variable and unique infectious manifestations. Bacterial infections of the eye are common and may be associated with significant morbidity. Predisposing factors, clinical presentation, microbiology, diagnosis, and treatment all depend on the ocular structure involved. Whether dealing with a relatively benign conjunctivitis, or a more threatening keratitis or endophthalmitis, accurate diagnosis and treatment can limit discomfort and disfigurement, and preserve vision.

INTRODUCTION

Bacterial infections of the upper respiratory tract are many and varied, ranging from benign pharyngitis to life-threatening epiglottis (Chow 2000; Berman 1995; Peterson and Thomson 1999). In spite of these differences, many concepts pertaining to host defense, pathogenesis, and bacterial virulence mechanisms are shared among diseases. In addition, anatomic features of the upper respiratory tract and normal commensal flora of epithelial surfaces are similar factors in all infections. Finally, infections of the upper respiratory tract may disseminate to distant foci, underscoring the potential seriousness of seemingly simple clinical conditions.

Infections of the upper respiratory tract can be divided into those that occur in the nasal airways and sinuses, middle ear and associated tissues, oral cavity, and in spaces adjacent to the oral cavity as abscesses (Table 1). Descriptions of specific infections will include the etiologies, epidemiology, unique defense mechanisms and pathogenesis, normal flora, a brief summary of clinical features, recommended antimicrobial therapy, and means of prevention. The goal of this chapter is to provide a complete understanding of factors contributing to the development and resolution of upper respiratory tract infection, the accurate and rapid diagnosis of infection, and treatment and prevention of subsequent infection.

ANATOMY

The upper respiratory tract is the area proximal to and including the epiglottis. It includes the middle ear, paranasal sinuses, nasopharynx, and oral cavity. Understanding the anatomy of the upper respiratory tract is necessary in order to understand the pathogenesis and prevention of disease at these sites (Thadepalli and Mandal 1984, 1988). The upper respiratory tract is composed of two distinct types of epithelial surfaces (Thadepalli and Mandal 1984; Thadepalli and Mandal 1988; Chow 2000). A stratified squamous epithelium lines the oropharynx and nasopharynx, and a respiratory epithelium, composed of ciliated columnar cells, goblet cells, and mucous glands, lines the paranasal sinuses and the middle ear. Stratified squamous epithelium is found in areas filled with normal microbial flora, representing sites easy to sample for bacteriologic culture. Epithelium of the sinuses and middle ear is usually sterile and is difficult to access if culture is needed.

The nasal airways and paranasal sinuses include the nasal septum, which divides the nose at the midline, turbinates, and four sinus complexes (Gwaltney 1996;

Table 1 *Upper respiratory tract diseases and etiologies*

Anatomic site/disease	Bacterial etiologies
Oral cavity	
Pharyngitis	*Streptococcus pyogenes*
	Occasionally other beta-hemolytic streptococci,
	Arcanobacterium haemolyticum, *Mycoplasma pneumoniae*
Diphtheria	*Corynebacterium diphtheriae*
Epiglottitis	*Haemophilus influenzae*
	Occasionally *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Staphylococcus aureus*, beta-hemolytic streptococci
Gingivitis	Mixed anaerobes, including spirochetes, *Actinobacillus actinomycetemcomitans*, *Eikenella corrodens*
Abscess	Mixed anaerobic, and aerobic bacteria, especially *Fusobacterium* spp. and viridans streptococci
Stomatitis	Anaerobaic bacteria, especially *Treponema vincentii*, *Prevotella melaninogenica*, and *Fusobacterium nucleatum*
Ludwig's angina	Streptococci, mouth flora
	Occasionally *H. influenzae*, staphylococci and facultative
	Gram-negative bacilli
Paranasal sinuses	
Sinusitis	*S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, *S. pyogenes*, other streptococci, *S. aureus*, anaerobic bacteria
Rhinoscleroma	*Klebsiella pneumoniae* subsp. *rhinoscleromatis*
Ear	
Otitis media and acute mastoiditis	*S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, *S. pyogenes*, *S. aureus*, anaerobes
Malignant external otitis	*Pseudomonas aeruginosa*
Abscesses adjacent to the oral cavity	
Peritonsillar, pharyngeal, retropharyngeal, and parapharyngeal	Mixed aerobic and anaerobic bacteria especially, *S. pyogenes*, *S. aureus*, *S. anginosus* (*milleri*) group
Lemierre's syndrome	*F. necrophorum*, other anaerobes
Suppurative paratitis	*S. aureus*, viridans streptococci, anaerobic bacteria

Wald 1996; Thadepalli and Mandal 1988; Thadepalli and Mandal 1984). The inferior, middle, and superior turbinates are three shelf-like projections that extend from the septum. Beneath the middle turbinate is a meatus that drains the maxillary, anterior ethmoids, and frontal sinuses. Beneath the superior turbinate is a meatus that drains the posterior ethmoids and sphenoid sinuses. The lacrimal duct drains to the inferior meatus. The maxillary sinus has a volume of approximately 15 ml and drains through an ostium high on the medial wall of the sinus. This positioning impedes normal gravitational drainage and, most likely, predisposes to bacterial infection. The tubular passage that connects the ostium to the meatus is called the infundibulum. The ethmoid sinus is composed of multiple cells, each of which drains by a separate ostium into the middle meatus. The frontal sinus is not fully developed until late adolescence. The sphenoid sinuses are located just behind the posterior ethmoids. The sphenoid and frontal sinuses can be a source for the spread of infection to the central nervous system.

The relevant structures of the ear include the external auditory canal, the tympanic membrane (eardrum), middle ear, mastoid, and Eustachian tube (Hendley 2002). The oral cavity includes the nasopharynx, pharynx, epiglottis, tongue, teeth, periodontium, and adjacent salivary and parotid glands (Roscoe and Chow 1988).

DEFENSE MECHANISMS

Protective mechanisms found in the upper respiratory tract include the primary defenses that are constantly active and secondary mechanisms that are activated or recruited at the time of infectious insult (Roscoe and Chow 1988). Primary defense mechanisms include the anatomy of the upper airways, epithelial surfaces, mucociliary clearance, and soluble factors in airway secretions, such as degratory enzymes, complement, and immunoglobulins (Roscoe and Chow 1988). Secondary mechanisms include recruitment of polymorphonuclear leukocytes and lymphocytes and the secretion of chemical mediators of inflammation by these cells (Chow 2000).

During breathing, the turbulence of air flowing through the nasal turbinates, nasopharynx, and oropharynx results in the sedimentation of bacteria within the upper respiratory tract. Tight junctions between epithelial cells provide an efficient barrier to bacterial penetration. The epithelium is continually

replenished if damaged. Throughout the nasal sinuses, middle ear, and Eustachian tubes, mucus-secreting cells secrete a blanket of mucus that is propelled along toward the oropharynx by ciliated cells, where it is coughed out or swallowed. Mucous contains soluble factors that augment the clearance of bacteria from normally sterile areas and prevents invasion past the epithelial layer (Feldman 2001). Other nonspecific defense mechanisms include the continuous cell shedding and turnover of the mucosal epithelium and the constant flow of saliva-containing lysozyme, lactoferrin, beta-lysin, lactoperoxidease, and other antimicrobial constituents (Chow 2000; Roscoe and Chow 1988). Immunoglobulin A (secretory IgA) is the predominant immunoglobulin in the upper respiratory tract. In addition to complement-independent neutralization of respiratory tract viruses, secretory IgA interacts with lysozyme and complement to improve bactericidal activity, augment bacterial adherence to mucus, and inhibit attachment to epithelial surfaces (Bernstein 1992; Roscoe and Chow 1988).

If primary defense mechanisms are unable to eradicate a bacterial pathogen, polymorphonuclear leukocytes and lymphocytes, constituting secondary defense mechanisms, are recruited to bolster the host's response (Roscoe and Chow 1988). Neutrophils migrate from the vascular compartment following the release of chemotactic factors by degraded bacteria. Bacterial antigen is transported to local lymph nodes either within phagocytic cells or free in afferent lymphatic fluid. Antigen processed in lymph nodes results in the expansion and differentiation of specific B and T cell clones. One to two weeks after infection, effector T and B cells migrate from lymph nodes to provide specific antibody locally in the respiratory tract.

PATHOGENESIS

Disease occurs when the balance between host and bacteria tips in favor of the microbes. This results from a defect in host defenses, an overwhelming inoculum of bacteria, or the presence of a novel bacterial virulence mechanism. Host defects range from increased colonization of the respiratory epithelium and failure of epithelial barriers to immunoglobulin deficiency and reduced phagocytic activity. In addition, environmental influences, such as tobacco smoke, may modify host defenses (Obeid and Bercy 2000).

Colonization of the upper respiratory tract is the first step in the pathogenesis of most bacterial infections. Individuals with poor nutrition, particularly vitamin A deficiency, and those with local areas of inflammation, such as gingivitis, are more likely to have increased bacterial colonization densities and a higher concentration of pathogenic species (Enwonwu et al. 2002). Antimicrobial therapy may change the relative numbers of bacterial commensals providing an advantage for some bacteria. It is also known that epithelial cells from patients with severe or chronic illness are more receptive to bacteria, especially gram-negative microorganisms (Niederman 1990).

Compromise of the respiratory epithelium results from trauma, radiation therapy, damage from chemotherapeutic agents, and environmental factors (Niederman 1990). Nasal intubation traumatizes the nasal airway, obstructs normal drainage, and provides a conduit for bacteria to gain access and to persist in deep respiratory spaces (Westergren et al. 1998a, b). Chemotherapy may damage or destroy rapidly dividing epithelial cells resulting in oral ulcers and breaches in barrier defense. Tobacco smoking, secondary tobacco smoke, and air pollution restrict ciliary clearance by direct toxicity, increase mucus production, and attract neutrophils (Obeid and Bercy 2000). Nasal discharge is more frequent in heavily polluted urban areas and more common upper respiratory tract infection is associated with increased pollution (Ng and Tan 1994).

BACTERIAL VIRULENCE MECHANISMS

Most bacteria that are pathogens in the upper respiratory tract are capable of adherence to and colonization of a mucus membrane. Factors that govern colonization are many and varied, including adherence characteristics of bacteria and epithelial cells, oxygen tension and oxidation-reduction potential, pH, age of patient, diet, oral hygiene, smoking habits, antimicrobial therapy, pregnancy, and genetic factors (Chow 2000). Colonization represents a 'period of waiting' for an opportunity to invade deeper tissues following trauma, or to be 'sequestered' in a closed space, such as a paranasal sinus or middle ear, as a result of inflammation caused by viral infection, allergy, or other insult (Bluestone 1996; Saez-Llorens 1994). Once positioned for disease, bacterial characteristics such as avoidance of complement deposition and phagocytosis, toxin production, synthesis of IgA proteases, and avoidance of mucociliary clearance augment disease severity (Kilian 1981).

Most bacteria are pathogenic throughout the upper respiratory tract, rather than one specific site (Table 1). *Streptococcus pneumoniae* resides in the pharynx and nasopharynx and persists in presumably sterile sites such as the paranasal sinuses and middle ear primarily because of an antiphagocytic capsule. *H. influenzae* possess fimbriae that bind to respiratory epithelium and mucin and reduce ciliary beating, which minimizes mucociliary clearance (Rodriguez et al. 2003). Group A streptococcal M protein binds to sialic acid moieties on mucin, followed by local invasion and toxin production that destroy local tissues (Ryan et al. 2001). Anaerobes provide 'colonization resistance,' i.e. prevent introduction or persistence of new bacterial populations, yet they are pathogens if they gain access to subepithelial spaces. The hallmark of anaerobic infection is the abscess. As a rule, multiple

anaerobic species, rather than a single species, are involved in upper respiratory infection. *Corynebacterium diphtheriae* is a specialized respiratory tract pathogen, capable of causing local disease in the pharynx or nasopharynx, yet exerting its most serious damage at distant sites as a result of toxin production (Hadfield et al. 2000). Viridans streptococci are included as part of a mixed etiology in abscesses, yet *Streptococcus mutans*, specifically, is the sole etiology of dental caries (Shaw 1987). Finally, *Staphylococcus aureus* is an abscess-forming, toxin-producing pathogen occasionally involved in infection of paranasal sinus, middle ear, and abscesses of the oropharyngeal spaces.

NORMAL FLORA

The anterior nares are colonized by staphylococci, micrococci, and miscellaneous *Corynebacterium* spp. (Roscoe and Chow 1988; Schuster 1999). The paranasal sinuses are normally sterile. In the mouth, anaerobes colonize periodontal areas along with a variety of other bacteria, including viridans group streptococci, *Haemophilus* spp., *Neisseria* spp., and diphtheroids (Schuster 1999; Roscoe and Chow 1988). The flora of the nasopharynx is much more complex. It may include *Streptococcus* spp., *Neisseria* spp., *Enterobacteriaceae*, *Bacteroides* spp., and *Fusobacterium* spp. (Sutter 1984). In addition, all individuals are colonized intermittently by one or more potential pathogens, such as group A streptococci, *S. pneumoniae*, *H. influenzae*, *N. meningitidis*, and *Moraxella catarrhalis* (Neto et al. 2003). Point prevalence surveys in communities demonstrate the ever-present nature of these pathogens.

Quantitative studies of the oral cavity indicate that certain species predominate in specific sites (Table 2) (Roscoe and Chow 1988; Schuster 1999). Obligate anaerobes constitute a large and important part of the oral flora. As an example, in the gingival crevice of healthy adults, microscopic counts average 2.7×10^{11} bacteria/gram wet weight, with anaerobes outnumbering facultative bacteria by a 8:1 margin (Chow 2000). Identification of specific genera shows *Streptococcus* spp., *Peptostreptococcus* spp., *Veillonella* spp., *Lactobacillus* spp., *Corynebacterium* spp., and *Actinomyces* spp. accounting for more than 80 percent of the cultivatable oral flora (Chow 2000). Other unique niches include *Streptococcus sanguis*, *Streptococcus mutans*, *Streptococcus mitis*, and *A. viscosus*, which preferentially colonize the surfaces of teeth (Chow 2000). *Streptococcus salivarius* and *Veillonella* spp. have a predilection for the tongue and buccal mucosa. *Fusobacterium* spp., *Porphyromonas* spp., *Prevotella* spp., and anaerobic spirochetes concentrate in the gingival crevice (Chow 2000). Facultative gram-negative bacilli are uncommon in the oral cavity of healthy adults; however, this group becomes a more prominent part of the flora in seriously ill, hospitalized, and elderly patients (Lipchik and Kuzo 1996). A number of exogenous factors may disturb the ecology of the mouth and nasopharynx. Antimicrobials can suppress normal flora, allowing yeasts and resistant bacteria to proliferate.

GENERAL CONSIDERATIONS: COLLECTION, TRANSPORT, AND PROCESSING OF SPECIMENS FOR BACTERIOLOGIC EXAMINATION

All specimens for bacteriologic culture should be collected from the specific site of inflammation, as free of contaminating flora as possible (Carroll and Reimer 1996; Peterson and Thomson 1999; Thomson and Miller 2003). In practice, most specimens from the upper

Table 2 *Oral flora*

Site	Predominant bacteria	Bacteria present but not predominant
Gingiva	Viridans group streptococci	Anaerobic gram-negative bacilli
	Lactobacilli	Other aerobic and anaerobic bacteria
	Anaerobic gram-positive rods	
	Anaerobic cocci	
Tongue	Viridans group cocci	Anaerobic gram-negative bacilli
	Lactobacilli	Anaerobic gram-positive cocci
	Anaerobic gram-negative cocci	Anaerobic gram-positive rods
		Other aerobic and anaerobic bacteria
Saliva	Viridans group cocci	Lactobacilli
	Anaerobic cocci	Anaerobic gram-positive bacilli
		Anaerobic gram-negative bacilli
		Other aerobic and anaerobic bacteria
Dental plaque	Viridans group streptococci	Anaerobic cocci
	Lactobacilli	Anaerobic gram-negative bacilli
	Anaerobic gram-positive bacilli	Other aerobic and anaerobic bacteria

Data from Chow (2000), Roscoe and Chow (1988), and Schuster (1999).

respiratory tract will contain at least low numbers of contaminating bacteria. Purulence should be aspirated or gently washed and aspirated. Sterile, nonbacteriostatic saline is an acceptable wash/lavage fluid. Specimens for anaerobic culture are collected by aspiration (Thomson and Miller 2003). Oxygen-free transport vials should be used to hold the aspirate during transport to the laboratory regardless of how quickly this will occur. Specimens for the detection of aerobic and facultative bacteria may be collected with a swab only when absolutely necessary, e.g. pharyngeal swab.

Specimens must be transported to the laboratory as quickly as possible. Receipt within 1 h is optimal (Thomson and Miller 2003; Carroll and Reimer 1996). Longer transport requires a holding medium. Specimens should not be allowed to dry or be frozen. Refrigerated or 'on-ice' temperature (approximately 40°C) is used unless anaerobes or *H. influenzae* are expected. Pathogenic *Neisseria* spp., *H. influenzae*, *S. pneumoniae*, and anaerobes are especially sensitive to extended holding and transport (Thomson and Miller 2003).

Once in the laboratory, processing includes a gram-stained smear, whenever purulence is submitted from an abscess or closed space, and a culture using appropriate media for the pathogens suspected. Gram stain results are used to determine inflammation and the presence of morphotypes suggesting a potential pathogen. Gram stain results are important when selecting empiric therapy, previous antimicrobial therapy inhibits growth, or anaerobes are present but have not survived exposure to oxygen during collection or transport.

Hospital microbiology laboratories are equipped to perform usual aerobic and anaerobic cultures. Staphylococci, streptococci, and nonfastidious gram-negative bacilli as predominant bacterial populations are readily detected. Less common pathogens, such as *Arcanobacterium haemolyticum*, *Neisseria gonorrhoea*, and *Corynebacterium diphtheriae*, can be detected by culture, stain, or molecular methods but only when the laboratory is notified in advance that a specific microorganism is being sought. Multiple anaerobes in mixed culture are not readily isolated and identified with usual methods. Newer selective media and techniques have been introduced to identify specific anaerobic pathogens in oral infections (Moore and Moore 1994; Chow 2000). These are available in a limited number of research, university or commercial settings. A recent, comprehensive review of collection, transport, and processing for bacterial specimens is available.

INFECTIONS OF THE ORAL CAVITY

Streptococcal pharyngitis

Pharyngitis is one of the most common reasons for physician visits among pediatric patients, with the group A streptococcus (*S. pyogenes*) the most likely treatable etiology (Gerber 1998). However, considering all patient groups and etiologies, including viruses, group A streptococci may account for as few as 5 percent of cases of pharyngitis (Carroll and Reimer 1996). Group A streptococcal pharyngitis is important not only because of the morbidity associated with acute disease but also because it may be followed by nonsuppurative sequelae (acute rheumatic fever or acute glomerulonephritis). Accurate detection and treatment of group A streptococcal pharyngitis is necessary to shorten the duration of symptoms, prevent the spread of the organism to other patients, prevent nonsuppurative sequelae, and avoid antimicrobial therapy in patients with viral infections (Gerber 1998). In spite of the frequency of disease and the potential for morbidity, a surprising number of practical questions dealing with the disease and its diagnosis remain unanswered.

Streptococcal pharyngitis is caused by *S. pyogenes*, a Lancefield group A Streptococcus based on cell-wall carbohydrate analysis. Group A carbohydrate is composed of N-acetylglucosamine linked to a rhamnose polymer backbone (Cunningham 2000). Disease is spread by person-to-person contact with infectious nasal or oral secretions, and is more common in situations of crowding. Disease occurs primarily in children between 5 and 15 years of age, mostly during winter and spring months in temperate climates (Gerber 1998). Further identification of group A streptococci can be performed by typing on the presence of M protein in the cell wall or by sequencing the *emm* gene that encodes the M protein (Bisno 1991; Bisno 2001). Currently, more than 80 M protein serotypes have been identified. Typing demonstrates that multiple serotypes circulate in a community at any one time (Haukness et al. 2002). During a 3-month winter period, typing of 63 group A streptococcal strains from three large pediatric practices in the Chicago area identified 16 different pulsed-field gel electrophoresis patterns. The resurgence of invasive, life-threatening streptococcal necrotizing fasciitis, and toxic shock over the past 15 years has stimulated a study of community pharyngeal strains to detect the location and prevalence of potentially invasive strains. Invasive strains constitute 25 percent of pharyngeal pathogens circulating in the community (Haukness et al. 2002).

M protein is the chief virulence factor of group A streptococci (Bisno 1991; Bisno 2001). Strains rich in M protein resist phagocytosis by polymorphonuclear leukocytes. M protein exerts its antiphagocytic effect by diminishing complement activation by the alternative complement pathway, thus limiting the deposition of complement on the bacterial surface (Bisno 1991; Bisno 2001). Immunity to infection is associated with the development of opsonic antibodies to antiphagocytic epitopes of M protein and, with few exceptions, such immunity is type-specific. Immunity lasts for many years, possibly for the life of the patient. In addition,

lipoteichoic acid is expressed on the surface of group A streptococci and is the adhesin responsible for binding of the organism to fibronectin present on the surface of oral epithelial cells (Bisno 1991). The streptococcal cell wall is surrounded by a hyaluronic acid capsule that is also antiphagocytic, serving as an additional virulence factor. Strains with large capsules are mucoid colonies on blood agar plates. Group A streptococcal strains that are both rich in M protein and heavily encapsulated are readily transmitted from person to person and tend to produce severe infections (Bisno 2001).

Patients with group A streptococcal pharyngitis present with sore throat (usually of sudden onset), pain on swallowing, and fever (Gerber 1998). Headache, nausea, vomiting, and abdominal pain (especially in children) also may be present. Clinical examination reveals tonsillopharyngeal erythema, with or without exudate, a red, swollen uvula, petechiae on the palate, and tender, enlarged anterior cervical lymph nodes. Tonsils, if present, are enlarged and erythematous. When a fine, diffuse red rash accompanies streptococcal pharyngitis, the syndrome is called scarlet fever (Gerber 1998).

The gold standard laboratory diagnostic test for group A streptococcal infection is the throat culture (Gerber 1998). If performed correctly, it has a sensitivity of 90–95 percent. Unfortunately, the culture takes 24–48 h to complete. If the patient leaves the physician or healthcare facility office with a prescription for antibiotics, the treatment would then begin before the microbial entity is known. In the age of emerging drug resistance, unnecessary antimicrobial use must be avoided. As a result, rapid streptococcal detection methods were developed to give nearly immediate results allowing for antimicrobial decision making while the patient is in the office or clinic (Peterson and Thomson 1999). Many rapid direct tests for group A streptococci are commercially available, including enzyme immunoassay (EIA), optical immunoassay, and nucleic acid-based probe assays (Thomson and Miller 2003). Although specificities are >95 percent, the reported sensitivities of EIAs and an optical immunoassay vary between 60 and 95 percent but can be as low as 31 percent. The nucleic acid-based assay has a sensitivity greater than 90 percent. When a rapid test is requested, two throat swabs should be collected. If only one swab is received, the culture plate should be inoculated first. Material remaining on the swab is used for the direct test. If the rapid test is positive, the second swab can be discarded, but if the rapid test is negative, the second swab must be used for culture to confirm the negative direct test (Gerber 1998; Thomson and Miller 2003). The nucleic acid-based probe test is considered sensitive and specific enough by many to obviate the need for confirmatory culture (Thomson and Miller 2003). A position paper by representatives of the American Academy of Family Physicians, the American College of Physicians–American Society of Internal Medicine, and the Centers for Disease Control and Prevention, states that rapid tests do not require confirmatory culture when used with specimens from adult patients (Cooper et al. 2001). This recommendation does not hold for specimens from children.

To culture group A streptococci, either sheep blood agar or selective blood agar may be used (Thomson and Miller 2003). Selective agar makes the organism easier to visualize by inhibiting the accompanying flora but may delay the appearance of colonies of *S. pyogenes*. Cultures should be incubated for 48 h at 35°C in an environment of reduced oxygen achieved by incubating anaerobically, in 5 percent CO2, or in air with multiple 'stabs' through the agar surface. Stabbing the agar surface with the inoculating loop pushes inoculum-containing streptococci below the surface, where the oxygen concentration is reduced compared with ambient.

Group A streptococci are uniformly susceptible to penicillin in vitro and the treatment of choice for acute group A streptococcal pharyngitis remains penicillin, as recommended by the American Heart Association, the Committee on Infectious Diseases of the American Academy of Pediatrics, and the World Health Organization (Gerber 1998). Cephalosporins and macrolides, such as erythromycin, are recommended in patients unable to take penicillin. Certain antimicrobials are not recommended for the treatment of group A streptococcal pharyngitis. Tetracyclines and trimethoprim-sulfamethoxazole have been shown to be ineffective in the treatment of this infection. Although in vitro testing is not necessary for penicillin, worldwide surveys show that up to 30 percent of stains are resistant to erythromycin and other macrolides (Alos et al. 2003; Hoban et al. 2003).

During the winter and spring in temperate climates, up to 20 percent of asymptomatic school-aged children may be streptococcal carriers (McEwan et al. 2003; Kaplan et al. 1981; Gerber 1998). These individuals have group A *Streptococcus* in their pharynx but have no evidence of immunologic response to this organism. They may be colonized for several months, and during that period they may experience episodes of intercurrent viral pharyngitis. When tested, these patients have group A streptococci in their pharynx and would seem to be suffering from acute streptococcal pharyngitis. Streptococcal carriers are unlikely to spread the organisms to their close contacts and are at very low risk, if any, of developing suppurative or nonsuppurative complications (Gerber 1998). Streptococcal carriers do not ordinarily require antimicrobial therapy. When eradication of streptococcal carriage is desirable, a short course of rifampin in conjunction with penicillin or a 10-day course of oral clindamycin have been shown to be effective (Gerber 1998).

Non-group A streptococcal pharyngitis caused by beta-hemolytic streptococci groups B, C, G, and F have

been reported (Peterson and Thomson 1999). Added to this list of uncommon causes of bacterial pharyngitis are mixed anaerobes (gangrenous pharyngitis), *N. gonorrhoeae*, *C. diphtheriae*, *Arcanobacterium haemolyticum*, *Yersinia pestis*, *Francisella tularensis*, *Mycoplasma pneumoniae*, *Chlamydophila psittaci*, and *C. pneumoniae* (Peterson and Thomson 1999). The clinical laboratory does not routinely look for any of these other agents in throat swabs, except when specifically requested by the clinician.

Diphtheria

Although much less common than streptococcal pharyngitis, *C. diphtheriae* can still be isolated from patients with a sore throat as well as those with a more serious systemic disease. Epidemic diphtheria re-emerged in the former Soviet Union beginning in 1990, resulting in approximately 125 000 cases and 4 000 deaths between 1990 and 1995 (Markina et al. 2000). The number of new cases began to decrease in 1996 following a World Health Organization strategy to vaccinate 90 percent of people aged 3 years or older (Markina et al. 2000). The introduction of new strains into countries with no endemic disease from exogenous reservoirs can cause outbreaks in developing nations, homeless populations, or in specific communities where vaccination is not accepted (Galazka 2000; Harnisch et al. 1989). The changing epidemiology of diphtheria includes the high proportion of infected adults, a progressive spread of disease from urban centers to rural areas, and transition from well-distinguished outbreaks to a more generalized epidemic (Galazka 2000).

The upper respiratory tract mucosa is the most common site of infection with *C. diphtheriae* in children but was a rare site for localization in adults patients in the epidemic that occurred in the former Soviet Union (Hadfield et al. 2000). In adults with oral mucosal lesions, buccal mucosa, upper and lower lips, hard and soft palate, and the tongue were sites of infection. *C. diphtheriae* localizes in the upper respiratory tract, ulcerates the mucosa, and induces the formation of an inflammatory pseudomembrane. The pseudomembrane is initially white, becoming a dirty gray color over time. Late in the course of infection the membrane may have patches of green or black necrosis. The growth of the organism remains localized, but exotoxin is absorbed and is disseminated through the blood to evoke severe systemic pathology. The exotoxin inhibits cellular protein synthesis by stimulating adenosine diphosphate ribosylation, thus inactivating protein synthesis elongation factor 2 (EF-2) (Harnisch et al. 1989).

The microbiologic diagnosis of diphtheria is designed to provide early and accurate diagnosis, identification of contacts and carriers, and appropriate clinical management (Efstratiou et al. 2000). The recommended microbiologic procedure includes obtaining a clinical specimen from the throat and nasopharynx. If present, membranous material should be sampled, including material from beneath the membrane. Blood agar and selective tellurite medium (Hoyle's tellurite medium is recommended) should be used (Efstratiou et al. 2000). Most normal flora will be inhibited on the tellurite medium allowing only *C. diphtheriae* and some other corynebacteria, staphylococci, and yeasts to be identified by the production of black colonies. The diagnosis of diphtheria on the basis of direct microscopy of a smear is unreliable because both false-positive and false-negative results may occur (Efstratiou et al. 2000). Rapid screening tests recommended for the differentiation of potentially toxigenic species of corynebacteria (*C. diphtheriae*, *C. ulcerans*, and *C. psuedotuberculosis*) are the presence of cystinase and the absence of pyrazinamidase activity (Efstratiou et al. 2000). Although there are four biotypes of *C. diphtheriae* (*C. diphtheriae* var. *gravis*, var. *mitis*, var. *belfanti*, and var. *intermedius*), biotyping is of limited use in epidemiologic investigations because discrimination is poor (Efstratiou et al. 2000). The minimum laboratory information required to report a specimen as positive for *C. diphtheriae* is as follows: Catalase-positive (most biotypes), urea-negative, nitrate-positive (except biotype *belfanti*), pyrazinamidase-negative, and cystinase-positive (Efstratiou et al. 2000). They will also ferment glucose, maltose, and starch (Table 3).

Testing for toxigenicity, which detects the phage-encoded exotoxin, is the most important test and should be carried out without delay on any suspect isolate that

Table 3 *Laboratory identification of* Corynebacterium diphtheriae *and related species*

			Gelatin

C. pseudotuberculosis	–	+	–	+	+	–	–

Data from Efstratiou et al. (2000).

is found by routine screening or while investigating a possible case. The potentially toxigenic species (*C. diphtheriae*, *C. ulcerans*, and *C. pseudotuberculosis*) acquire this characteristic when infected by bacteriophage. Although rapid polymerase chain reaction (PCR) assays have been used to detect biologically active fragment A of the toxin, positive results must be confirmed by phenotypic testing with the modified Elek immunoprecipitation test, since strains may possess toxin genes but do not express biologically active toxin (Efstratiou et al. 2000).

Epiglottitis

Acute bacterial epiglottitis, defined as inflammation and edema of the epiglottis, can result in life-threatening airway obstruction (MayoSmith et al. 1986). Inflammation can also occur in the arytenoid cartilage (paired jug or pitcher-shaped structures that move vocal cords apart) or pharyngeal wall, resulting in acute supraglottitis (Donnelly and Crausman 1997). Acute epiglottitis in children is caused by *H. influenzae* type b in most cases. In bacteremic cases an even higher percentage of cases is caused by *H. influenzae* (Bamberger and Jackson 2001). In adults, only 25 percent of cases are associated with *H. influenzae*. Disease caused by *S. pneumoniae*, bete-hemolytic streptococci (groups A, B and C), *S. aureus*, *H. parainfluenzae*, and *N. meningitidis* have been described (Warner and Finlay 1985; Sack and Brock 2002). Unusual pathogens such as *Klebsiella pneumoniae* and *Pasteurella multocida* have been reported in immunocompromised patients (Wine et al. 1997).

Epiglottitis occurs in people of all ages, with most cases found in children 2–7 years of age before widespread use of the *Haemophilus influenzae* type b (Hib) vaccine (Bamberger and Jackson 2001). Annual attack rates of 2–13 per 100 000 children were reported. With the introduction of the vaccine in the mid 1980s, the incidence of acute epiglottis in the pediatric population has decreased to 0.3–0.6 per 100 000. The incidence in adults is reported to be two to three cases per 100 000 and possibly increasing due to greater awareness and recognition of disease in adults (MayoSmith et al. 1986; Bamberger and Jackson 2001). For adults, the mean age at the time of presentation of disease ranges from 42 to 50 years. Cigarette smoking in diseased patients is more frequent than in the general population. Although cases occur in all months, spring and winter seasonal peaks have been reported (Bamberger and Jackson 2001).

Haemophilus species are exclusively adapted to the human mucosal membranes (Kilian 1981). *H. influenzae* is the species most frequently associated with disease in humans. The portal of entry for *H. influenzae* is the nasopharynx following person-to-person spread via respiratory droplets. Upper respiratory tract colonization rates for all species in humans may be as high as 50 percent. Nonencapsulated *H. influenzae* and *H. parainfluenzae* are the species most commonly found as commensals. Colonization by serotype b encapsulated *H. influenzae* strains is uncommon in healthy children and adults (Bamberger and Jackson 2001). The occurrence of disease after acquisition of an *H. influenzae* serotype b strain depends on the ability to colonize the nasopharynx and the ability to infect target tissue. The presence of the polysaccharide capsule and the production of IgA proteases are postulated to play a role in the pathogenesis of serotype b strains.

Epiglottitis in a previously well child is characterized by the sudden onset of high fever, severe sore throat with dysphagia, and drooling (MayoSmith et al. 1986; Ward 2002). In adults, epiglottitis manifests as a sore throat with odynophagia. Inflammation in adult disease is not confined to the epiglottis, as is the case with children, but rather can also affect other laryngeal and oropharyngeal structures. Consequently, a more accurate term than epiglottitis for adults is supraglottitis (Donnelly and Crausman 1997). If the diagnosis of epiglottitis is in question (pediatric or adult patient), radiography may be used but only if personnel experienced in intubation and resuscitation equipment are available, since airway compromise may occur (MayoSmith et al. 1986). Intensive care unit (ICU)-level care for the initial 24–48 h is prudent. In addition, oropharyngeal examination should not be performed, attempts should not be made to lay the patient down, and venipuncture should be avoided until the patient's airway is secured. In one review of acute epiglottitis in adults, two of 44 patients receiving medial treatment with no artificial airway died of sudden respiratory failure (MayoSmith et al. 1986). Epiglottitis must be differentiated from viral laryngotracheitis, bacterial tracheitis, diphtheria, and a foreign body lodged in the larynx. Penetrating pharyngeal injury and parapharyngeal or paravertebral abscess may mimic epiglottitis (Chung 2002).

The likelihood of beta-lactamase-producing *H. influenzae* and the inclusion of multiple etiologies in adults has led to the practice of empiric treatment with a beta-lactamase-resistant, third-generation cephalosporin (Bamberger and Jackson 2001). Most disease in children can be prevented by routine use of Hib conjugate vaccine (McEwan et al. 2003).

Gingivitis/Vincent's disease

Inflammation of the gingiva begins with irritation and microbial invasion of the gums (Fenesy 1998; Chow 2000). Subgingival plaque is always present. Simple gingivitis is characterized by swelling and thickening of the gingiva with a tendency for the gums to bleed after eating or toothbrushing. There is usually no pain. Patients with acute necrotozing gingivitis, also known as Vincent's disease or trench mouth, experience pain in

the gingiva that interferes with normal chewing. Necrosis of the gingiva between the teeth, a grayish pseudomembrane, and a characteristic halitosis with altered taste are present. Fever, malaise, and regional lymphadenopathy may occur (Fenesy 1998).

Vincent described the disease in the late nineteenth century as a fusospirochetal infection due to the prominence of these microorganisms in smears of material removed from the lesion (Loesche and Grossman 2001). Mixed aerobic and anaerobic flora, especially spirochetes, with some that have never been cultured, *Fusobacterium* spp., *Prevotella* spp. and *Porphyromonas* spp., *Actinobacillus acintomycetemcomitans*, and *Eikenella corrodens* are frequently implicated as prominent etiologies of acute necrotozing ulcerative gingivitis and other periodontal diseases (Loesche and Grossman 2001; Darby and Curtis 2001).

Patient defense mechanisms against gingivitis include the highly vascular gingival tissue that presents an oxidative barrier to the penetration of anaerobic flora from the dental plaque (Loesche and Grossman 2001). While certain bacteria, such as *A. actinomycetemcomitans*, can be detected within the tissue, they are rarely able to cause tissue necrosis without the association of other anaerobic bacteria. Conditions that cause vasoconstriction of peripheral arterioles, such as smoking and stress, are risk factors for periodontal disease, most likely because of reduced blood flow allowing invading anaerobes to survive (Loesche and Grossman 2001; Fenesy 1998).

Treatment includes local debridement and lavage with oxidizing agents, which usually brings relief from pain within 24 h. Antimicrobial therapy with penicillin or metronidazole is highly effective (Chow 2000; Duckworth et al. 1966; Loesche and Grossman 2001).

Periodontal abscess

Periodontal disease is a general term that refers to all diseases involving the periodontum (supporting structures of the teeth) (Suzuki 1988). Subgingival plaque and gingivitis precede infection of the underlying supporting tissue, ultimately leading to destruction of the periodontium and permanent loss of teeth. Chronic inflammation of the periodontium is the major cause of tooth loss in adults. Periodontal infections generally drain freely, resulting in little or no discomfort to the patient. The microbial specificity in different periodontal infections has only recently been appreciated (Chow 2000; Moore and Moore 1994). In the healthy periodontum, normal flora is sparse and consists mainly of gram-positive bacteria such as *S. oralis*, *S. sanguis*, and *Actinomyces* spp. In patients with gingivitis, the predominant subgingival flora includes anaerobic gram-negative bacilli, *Capnocytophaga* spp., and *Peptostreptococcus* spp. With progression to periodontitis, the flora increases further in complexity, with the addition of spirochetes (*Treponema denticola*), *Porphyromonas gingivalis*, and *A. actinomycetemcomitans*. With periodontal abscess, the polymicrobial flora also includes *Fusobacterium* spp. and viridans streptococci. Facultative gram-negative bacilli and staphylococci are uncommon in all periodontal infections. This microbial specificity has been defined by improved sampling and anaerobic culture techniques (Moore and Moore 1994; Maiden et al. 1997). The progression from supragingival dental plaque to subgingival dental plaque represents saccharolytic bacteria that can adhere to the tooth versus asaccharolytic bacteria that do not adhere to teeth, respectively. Periodontitis can be treated with systemic tetracycline or metronidazole combined with local treatment involving root debridement and surgical resection of inflamed tissues. Loculated abscesses must be drained (Loesche and Grossman 2001).

Stomatitis

Stomatitis refers to the inflammation of the oral mucosa including the buccal and labial mucosa, palate, tongue, floor of the mouth, and the gingivae. Severe forms occur in those with underlying malnutrition, debility, or immunocompromising disease such as human immunodeficiency virus (HIV) (Wexler et al. 1997). A small gingival ulcer progresses to a necrotic ulcer and then to a painful cellulitis of the lips and cheeks. Sloughing of necrotic soft tissues occurs, exposing underlying bone and teeth. *Borrelia vincentii*, *Prevotella melaninogenica*, and *Fusobacterium nucleatum* are common in the lesions (Chow 2000). Other bacteria are commonly seen in biopsy specimens but can not be cultured and identified. At this time, a comprehensive understanding of the pathogens involved does not exist. Treatment involves debridement, irrigation with a povidone–iodine solution, and systemic antibiotics with anaerobic coverage such as metronidazole, amoxycillin with clavulanic acid, or clindamycin (Chow 2000, Patton and van der Horst 1999).

Ludwig's angina

Ludwig's angina is a cellulitis of the submandibular, sublingual, and submental regions (Hartmann 1999; Spitalnic and Sucov 1995). In most patients, the infection originates from a dental focus. Clinical features include fever, toxicity, and a rapidly progressive edema in the floor of the mouth and the anterior neck. Elevation of the tongue impedes swallowing, and airway obstruction may be fatal. Streptococci and mouth flora are the most common etiologic agents, but *H. influenzae*, staphylococci, and gram-negative bacilli have also been implicated. Broad-spectrum antimicrobial therapy is needed

and tracheostomy may be necessary to preserve the airway (Barakate et al. 2001).

PARANASAL SINUSES AND ASSOCIATED AIRWAYS

Sinusitis

Sinusitis is a common disease with significant morbidity. It is estimated that 20 million cases of acute community-acquired bacterial sinusitis occur each year in the USA (Gwaltney 1996). In addition, bacterial nosocomial sinusitis is commonly recognized. Although bacterial infections of the sinuses are common, they are greatly overdiagnosed by patients and physicians. An understanding of the etiology, pathogenesis, and methods of diagnosis are important factors in preventing overdiagnosis.

Predominant pathogens in adult acute maxillary sinusitis are *S. pneumoniae* and *H. influenzae*, accounting for more than 50 percent of cases. *M. catarrhalis*, other streptococci such as *S. pyogenes* and viridans streptococci, *S. aureus*, and anaerobic bacteria account for the remainder of cases (Table 4). *Moraxella catarrhalis* is more common in pediatric patients, while anaerobes are less common. In spite of comprehensive bacteriologic analysis, cultures are negative from a high percentage of patients with the clinical diagnosis of sinusitis (Gwaltney 1996; Gwaltney et al. 1992). Some of these patients may have had viral infection rather than bacterial, and many may have had ostial occlusion preventing infected inflammatory material from draining and being accessible for culture. Others have suggested that *Chlamydophila pneumoniae* and *Mycoplasma pneumoniae* represent likely etiologies when bacterial cultures are negative (Gwaltney 1996). These bacteria have not been confirmed as causes of sinusitis by careful aspiration of sinus material and are not established as true pathogens. Although the relative importance in sinus infection of different bacteria has not changed in decades, there have been important changes in resistance to antimicrobials. The emergence of beta-lactamase production by *H. influenzae* and *M. catarrhalis* and the emergence of multiply resistant pneumococci have focused significant attention on the management of sinus infections (Brook 2002).

Table 4 *Etiology of adult and pediatric acute sinusitis*

Etiology	Approximate percentage of cases	
	Adult patients	Pediatric patients
Streptococcus pneumoniae	30	36
Haemophilus influenzae	20	23
Moraxella catarrhalis	5	20
Staphylococcus aureus	4	0
Streptococcus pyogenes	2	<5
Anaerobic bacteria	6	0
Other bacteria	5–10	<5
Viruses	25	3–5

Data from Bamberger and Jackson (2001) and Gwaltney (1996).

The bacteriology of chronic sinusitis is less clear because many of the patients have had prolonged and varied courses of antimicrobial therapy and culture material has not been collected by endoscopic or surgical drainage that avoids contamination with airway flora. Nevertheless, anaerobic pathogens are common in some studies of adults and uncommon in others (Bamberger and Jackson 2001; Nadel et al. 1998). Bacteria more frequently detected in chronic sinusitis include *S. aureus*, facultative gram-negative bacilli (*Enterobacteriaceae*) and *Pseudomonas aeruginosa*, and nonpneumococcal streptococci (Nadel et al. 1998).

Sphenoid, or frontal sinusitis, differs from acute maxillary sinusitis in that *S. aureus* is a frequent pathogen, in addition to pneumococci, *H. influenzae*, and anaerobic streptococci. Chronic bacterial sphenoid sinusitis is caused most commonly by gram-negative pathogens (Lew et al. 1983).

Bacteria associated with nosocomial sinusitis include usual nosocomial pathogens such as *P. aeruginosa*, *Acinetobacter* spp., enteric gram-negative bacilli, and *S. aureus*. Streptococci and anaerobes are less common. (Westergren et al. 1998a, b). Sinusitis is reported to be present in as many as 68 percent of HIV infected patients, especially those with CD4 cell counts below 200 per mm^3. A variety of bacterial and nonbacterial pathogens can be detected, with *P. aeruginosa* a common bacterial etiology (Rubin and Honigberg 1990). *P. aeruginosa* and *S. aureus* are common in patients with cystic fibrosis or syndromes that compromise ciliary motility (Mak and Henig 2001; Bertrand et al. 2000).

The pathogenesis of sinus infection is dominated by mucosal swelling and mechanical obstruction that occur following upper respiratory tract viral infection (Gwaltney 1996). Seventy-seven percent of patients have occlusion of the infundibulum and 87 percent have sinus cavity disease accompanying the common cold (Gwaltney 1996; Gwaltney et al. 1994). Also important is the fact that rhinovirus infection induces goblet cells to secrete an increased amount of thick mucus that is inadequately cleared by ciliary function. Thus, a major part of the disease process appears to be a function of mucocilliary clearance as a result of increased amounts of viscous material, which occurs in addition to infundibular and ostiomeatal obstruction (Gwaltney 1996). An estimated 0.5–2.0 percent of colds are complicated by bacterial infection of the sinuses arising from normal flora of the nasopharynx and nasal passages. Although the paranasal sinuses are normally sterile, transient inoculation with commensals from the nasal passages

can be effectively cleared by ciliary action within the sinus. Secretions and inflammation following rhinovirus infection, and presumably other viruses causing the common cold, impede effective clearing resulting in trapped bacteria in a 'closed' space (Puhakka et al. 1998; Diaz and Bamberger 1995; Monto et al. 2001).

Other less common causes of bacterial sinusitis include extension of dental infections into the maxillary sinus, ostial obstruction due to allergic rhinitis, anatomic abnormalities including as deviated nasal septum or nasal polyps, and barotrauma due to flying or deep-water diving (Bamberger and Jackson 2001). Immunodeficiency diseases also predispose patients to sinusitis, including HIV infection, diabetes, chronic granulomatous disease, and hypogammaglobulinemias. Risk factors for nosocomial sinusitis include nasogastric tubes and nasoendotracheal tubes (Rubin and Honigberg 1990; Westergren et al. 1998a).

Clinical features of sinusitis represent combined features of viral upper respiratory tract infection and bacterial sinusitis (Andre et al. 2002). Sneezing, rhinorrhea, nasal obstruction, facial pressure, and headache are common sinonasal complaints. In addition, those with confirmed acute community-acquired bacterial sinusitis are described to have purulent nasal discharge, a temperature of $\geqslant 38^{\circ}C$, facial pain or erythema, cough, and a decreased sense of smell (Gwaltney 1996).

Diagnosis of acute bacterial sinusitis is difficult despite modern technology (Gwaltney 1996; Andre et al. 2002). Differentiating allergy from bacterial infection and viral from bacterial etiology, and determining what specific bacterial etiology is involved, can be challenging. Sinus puncture provides definitive identification of etiology in cases serious enough to require invasive diagnostic techniques. Purulent sinus secretions carefully smeared and gram-stained have been shown to improve culture specificity (Jousimies-Somer et al. 1988). Morphotypes seen in the Gram stain, in association with polymorphonuclear leukocytes, predicted pathogens that eventually grew in concentrations above 1 000 CFU/ml on culture media. This suggests that smear, staining, and culture of sinus secretions may help differentiate bacterial from viral acute maxillary sinusitis. In addition, studies have shown that patients with sinus infection who have secretions containing *H. influenzae*, *M. catarrhalis*, or *S. pneumoniae* do benefit from antimicrobial therapy (Kaiser et al. 1996).

Appropriate antimicrobials given according to accepted regimens has been shown to reduce bacterial concentrations in the sinus cavity compared with incorrect antimicrobials or regimens (Gwaltney 1996). Because of the possibility of progressive damage to ciliated epithelium in the sinus, early therapy and eradication of a bacterial etiology are beneficial (Gwaltney et al. 1992; Hinni et al. 1992). Although multiply resistant pneumococci are an ever-increasing problem, therapy with amoxicillin-clavulante, an oral cephalosporin with maximal pneumococcal activity, or a newer fluoroquinolone are recommended antibacterial regimens (Pfaller et al. 2001; Poole 1997).

Prevention of acute sinusitis requires preventing upper respiratory tract viral infection and entry of nasal flora into the sinuses (Puhakka et al. 1998). To some extent, colds can be prevented by hygienic measures such as handwashing and covering one's mouth when sneezing. There is no proven measure for preventing secondary bacterial infection of the sinuses.

Rhinoscleroma

Rhinoscleroma is a chronic, progressive, disfiguring, and debilitating granulomatous infectious disease that has affected man for over 1 000 years (Hart and Rao 2000). It predominately affects the upper airways. It is caused by a gram-negative bacterium, *Klebsiella pneumoniae* subsp. *rhinoscleromatis*, most often referred to as *K. rhinoscleromatis*. Although test kits may not reliably identify this subspecies of *Klebsiella*, it can be differentiated from *K. pneumoniae* sensu stricto by a positive methyl red test and negative Voges-Proskauer, urease, citrate, and lysine decarboxylase tests (Toohill 1993).

More than 16 000 cases of rhinoscleroma have been reported since 1960 from most parts of the world (Hart and Rao 2000). It is found predominantly in rural areas and is more common in regions where socioeconomic conditions are poor. In developed countries in temperate zones, cases are detected but are generally imported. The disease has been widely reported from many Middle Eastern countries, tropical Africa, India, Southeast Asia, and Central and South America (Muzyka and Gubina 1971). Females are more commonly affected than males (ratio 13:1) and disease most commonly presents in the second and third decades of life (Hart and Rao 2000).

Disease usually occurs at the junction between epithelial surfaces, such as the interface between the squamous epithelium of the anterior nares and the deeper columnar ciliated epithelium (Hart and Rao 2000). Other explanations of disease prevalence include the fact that iron deficiency leads to squamous metaplasia, suggesting that poor nutrition and pregnancy may play a roll in the preponderance of disease occurring in women of childbearing age (Hart and Rao 2000) (Akhnoukh and Saad 1987).

Rhinoscleroma affects most areas of the respiratory tract (Hart and Rao 2000). The nose is involved in 95–100 percent of cases and the pharynx in up to half of cases. Occasionally, other areas of the respiratory tract are involved, such as the Eustachian tubes, sinuses, mouth, orbit, larynx, trachea, and bronchi. Although it may be considered an opportunistic infection in patients with acquired immunodeficiency syndrome (AIDS), there are no reports of dissemination despite low CD4-lymphocyte (Andraca et al. 1993; Paul et al. 1993). Rhinoscleroma is divided into three stages: catarrhal-

atrophic (referred to as ozaena), granulomatous, and sclerotic (Hart and Rao 2000). The first stage is characterized by a foul-smelling purulent nasal discharge. Most cases are diagnosed in the granulomatous stage as the patient complains of epistaxis and nasal deformity with lesions appearing as bluish-red, rubbery granulomas. Histologic examination during the granulomatous stage reveals Mikulicz cells, which are large macrophages containing vacuoles filled with bacteria.

Treatment involves surgical debridement and prolonged antimicrobial therapy. In vitro, *K. rhinoscleromatis* is susceptible to many antimicrobials. With most therapeutic regimens, relapse is common. Prolonged therapy with fluoroquinolones has produced the best results with low relapse rates (Hart and Rao 2000; Borgstein et al. 1993).

EAR

Otitis media and acute mastoiditis

Otitis media is a common reason for very young children to seek medical treatment. The peak age of disease is between 6 and 15 months of age. By the age of 7 years, 90 percent of children have had at least one episode of otitis media (Klein 1994). Otitis media is categorized as acute, serous, or chronic (Hendley 2002; Klein 1994; Shurin et al. 1983). Acute disease is characterized simply by suppuration in the middle ear, fever, ear pain, and a bulging tympanic membrane. Serous otitis media is defined as the presence of middle ear effusion behind an intact tympanic membrane without acute signs or symptoms. Chronic otitis media occurs when long-standing discharge through a perforated tympanic membrane is noted. It is important to understand that, in spite of the widespread use of antimicrobial therapy for otitis, acute mastoiditis remains the most common suppurative complication of acute otitis media (Klein 1994).

Streptococcus pneumoniae and *H. influenzae* are the most common etiologies detected in all patient groups. Many pneumococcal serotypes are involved and nontypeable strains of *H. influenzae* predominate, similar to strains found as normal upper respiratory tract flora in children and adults. *Moraxella catarrhalis* may be recovered in up to 10 percent of cases (Shurin et al. 1983). Other etiologies occasionally encountered include *S. pyogenes*, *S. aureus*, facultative gram-negative bacilli (Enterobacteriaceae), and anaerobes (Bluestone 1998). *Pseudomonas aeruginosa* is a common etiology in chronic suppurative otitis media (Chan and Hadley 2001). In addition, *Mycobacterium tuberculosis* is an occasional cause of chronic suppurative otitis media (Jeang and Fletcher 1983).

The pathogenesis of otitis media is multifactoral (Bluestone 1996). Prior or concurrent viral infection, host differences, anatomic factors, and environmental exposures all impact the pathogenesis of middle ear infection. Viral infection predisposes the patient to development of acute otitis media by causing Eustachian tube dysfunction and enhancing nasopharyngeal colonization with middle ear pathogens (Saez-Llorens 1994; Faden et al. 1998). Otitis media is more common at a young age, in patients with immature or impaired immunologic status, in those with upper respiratory allergy, in those with a familial predisposition or other siblings in the household, in males, in Native Americans and Australian Aborigines, and in babies who are bottle-fed (Bamberger and Jackson 2001). Otitis media is also more common in children who attend daycare and in those exposed to passive cigarette smoke. The pathogenesis of acute otitis media may be summarized as follows: The patient has an upper respiratory tract viral infection that results in congestion of the respiratory mucosa, including the nasopharynx and Eustachian tube, resulting in obstruction of the tube. Negative pressure in the middle ear develops, and, when prolonged, results in 'aspiration' of potential bacterial and viral pathogens into the middle ear. Because of the obstruction, clearance of infected middle ear fluid is impaired. Fluid accumulates in the middle ear, followed by bacterial growth and resulting inflammation. Suppurative and symptomatic otitis media result. A complete discussion of the pathogenesis of otitis media can be found in a review by Bluestone (1996).

Acute mastoiditis can be a natural extension and part of the pathological process of acute otitis media. In fact, the mastoid air cells are involved in many children who have acute otitis media (Bluestone 1998). Infection of the mastoid air cells usually resolves spontaneously or after effective antimicrobial treatment. The effusion within the mastoid air cells drains into the middle ear and, in turn, into the Eustachian tube. The communication between the middle ear and the mastoid air cells is narrow and is called the aditus-ad-antrum (Bluestone 1996, 1998). Functionally, the mastoid air cell system is a reservoir of gas for the middle ear and the narrow passage makes it difficult for middle ear infection to enter the mastoid. The aditus-ad-antrum can become obstructed as a result of swelling and granulation tissue. This swelling is implicated in the pathogenesis of acute mastoiditis. If the obstruction persists, mastoiditis with periosteitis (infection of the periosteum covering the mastoid process) can develop. This condition can lead to mastoid osteitis and further develop into infection of the temporal bone and intracranial cavity (Bluestone 1998).

Overall, 85 percent of cases of acute otitis media in children will resolve without antimicrobial therapy. Importantly, spontaneous resolution occurs in 90, 70, and 20 percent of cases caused by *M. catarrhalis*, nontypeable *H. influenzae*, and *S. pneumoniae*, respectively

(Faden et al. 1998). It is clear that the pneumococcus is the most important pathogen. It is also clear that pneumococci collected worldwide can be resistant to multiple antimicrobial agents (Zhanel et al. 2003; Muhlemann et al. 2003). Since the widespread use of antimicrobial agents to treat acute otitis media, the incidence of mastoiditis and other complications has decreased from 40 percent early in the twentieth century to less than 0.5 percent at present (Faden et al. 1998). Antimicrobial treatment of acute otitis media is recommended to prevent suppurative sequelae, shorten the time spent with middle ear effusion, and prevent recurrent disease. Amoxycillin remains an appropriate choice for first-line therapy for acute otitis media (Hendley 2002; Klein 1994; Berman 1995; Hoberman et al. 2002). For patients in whom amoxicillin is unsuccessful, second-line therapy should have demonstrated activity against penicillin-resistant *S. pneumoniae* as well as beta-lactamase-producing pathogens. Appropriate options include high-dose amoxycillin-clavulanate and ceftriaxone. Tympanocentesis is useful for identifying persistent and resistant pathogens (Hoberman et al. 2002). The pneumococcal conjugate vaccine was approved recently for use in children and should be administered to all children less than 2 years old. Introduction of this vaccine is likely to have some beneficial effect on the proportion of resistant *S. pneumoniae* isolates by decreasing carriage of vaccine-related serotypes (Pelton 2002). In addition, the possible use of fluoroquinolones in pediatric patients and the introduction of ketolides may impact therapeutic recommendations for acute otitis media (Pelton 2002).

Malignant external otitis

Malignant external otitis is a serious infection caused by *P. aeruginosa* that occurs primarily in elderly diabetic subjects. Infection can progress to a skullbase osteomyelitis with resultant cranial neuropathies. In spite of long-term systemic antimicrobial therapy, the disease is recurrent and may be associated with significant mortality (Rubin and Yu 1988).

Since the natural reservoir of *P. aeruginosa* is water, the accumulation of moisture in the external ear canal is the likely inciting event (*P. aeruginosa* is also the most common etiologic agent of chronic external otitis). Spread from the external canal occurs as infection crosses the cartilaginous-osseus junction into the temporal bone, bypassing the tympanic membrane and middle ear. Infection then passes to the mastoid. Because of its proximity to the initial site of infection, the facial nerve is the first, and often only, cranial nerve to be involved. Small-vessel disease that results in cutaneous hypoperfusion, diminished local host resistance, and increased susceptibility to infection, is a likely reason that most patients have malignant external otitis. The pathogenesis of malignant external otitis in nondiabetic patients appears related to immune dysfunction or a combination of impairments resulting from underlying disease or malnutrition (Rubin and Yu 1988).

Therapy should include surgery for local debridement and excision of foci of infection (Rubin and Yu 1988; Raines and Schindler 1980). *P. aeruginosa* can be cultured from specimens representing material from the external auditory canal and removed during surgical debridement. However, the mainstay of therapy is systemic antimicrobial therapy with two anti-pseudomonal drugs (such as antipseudomonal beta-lactam and aminoglycoside) for up to 8 weeks or more if extensive disease is present.

ABSCESSES ADJACENT TO AND ORIGINATING FROM THE ORAL CAVITY

Peritonsillar, pharyngeal, retropharyngeal, and parapharyngeal abscesses

Infections of the deep spaces of the neck are potentially serious because of the likelihood of spread to critical structures, such as major blood vessels and the mediastinum, leading to thrombosis, mediastinitis, purulent pericarditis, and pleural empyema (Peterson and Thomson 1999; Chow 1992; Parhiscar and Har-El 2001). Peritonsillar abscess is caused by mixed aerobic and anaerobic bacteria, with *S. pyogenes*, *S. aureus*, and *S. anginosus* group streptococci playing a prominent role (Fujiyoshi et al. 2001). Pharyngeal, retropharyngeal, and parapharyngeal abscesses involve structures extending into the neck that may be life-threatening. These infectious sites are associated with anaerobes, which outnumber aerobes three to one, with an average of more than seven bacterial species in the abscess material. As expected, oral flora cause these infections, primarily represented by *Peptostreptococcus* spp., *Prevotella* spp., *Porphyromonas* spp., *Fusobacterium* spp., and *Actinomyces* spp. Streptococci, primarily of the viridans group, are also important. When these abscesses develop in the hospitalized patient, *S. aureus* and various aerobic gram-negative bacilli are more likely to be involved (Peterson and Thomson 1999). Immediate surgical drainage and antimicrobial therapy directed at oral anaerobic flora and streptococci are indicated since complications can be life threatening (Parhiscar and Har-El 2001; Matsuda et al. 2002).

Lemierre's syndrome (jugular vein thrombophlebitis)

Lemierre's syndrome is a specialized oropharyngeal infection characterized by secondary septic thrombophlebitis of the internal jugular vein and frequent metastatic spread of infection (Chirinos et al. 2002).

Fusobacterium necrophorum, a normal inhabitant of the oral cavity, is the usual etiologic agent, along with other oral anaerobes that are occasionally detected. The disease progresses most commonly from pharyngitis, to local invasion of the lateral pharyngeal space, to internal jugular vein thrombophlebitis and subsequent metastatic complications involving the lungs, joints, liver, and mediastinal muscle. A swollen and/or tender neck and noncavitating pulmonary infiltrates in patients with recent or current pharyngitis are the most common findings. Blood collected by venipuncture and specimen representing material debrided during surgery, when performed, should be transported and cultured for aerobic and anaerobic bacteria. In the preantibiotic era the outcome was fatal with rapidly progressing septicemia. Mortality with antimicrobials and surgery (if necessary) is approximately 6 percent (Chirinos et al. 2002). Antimicrobial therapy with activity against anaerobic gram-negative bacilli and gram-positive cocci is recommended, such as metronidazole or clindamycin (Chirinos et al. 2002; Williams et al. 1998).

Suppurative parotitis

Acute suppurative parotitis (sialadenitis) is seen in very ill patients, especially those that are dehydrated, malnourished, elderly, or recovering from surgery (Thomson and Miller 2003; Raad et al. 1990). It is characterized by painful, tender swelling of the parotid gland. Purulent drainage may be evident at the opening of the duct of the gland in the mouth. *S. aureus* is the major pathogen, but on occasion viridans streptococci and oral anaerobes may play a role (Brook 2003). A chronic bacterial parotitis has been described that also is caused by *S. aureus*. Less often, other salivary glands may be involved, usually because of ductal obstruction. *Mycobacterium tuberculosis* may involve the parotid gland in conjunction with pulmonary tuberculosis (Mert et al. 2000).

INTRODUCTION

Despite the very large surface area of the lung and airways, few microorganisms colonize this tissue and cause disease. Thousands of microorganisms are inhaled with the air and aspirated with pharyngeal secretions during sleep (Kikuchi et al. 1994); for each of these, there is at least one of four possible outcomes. First, the microorganisms may be rapidly cleared from the lung. Second, they may lodge in the upper respiratory tract and asymptomatically colonize the site. Third, they may persist in regions that are normally sterile, such as below the larynx, as is observed in chronic obstructive pulmonary disease. Finally, they may penetrate epithelium and initiate parenchymal disease, as in pneumonia, or they may invade the bloodstream to cause systemic infection. Microbial load and host defenses are the subject of a constant balancing act. Successful microbes have adapted to avoid rapid clearance, gain nutrients, and survive in the respiratory tract sufficiently to grow and disseminate to other hosts. The aim of host defenses is to maintain the sterility of the gas-exchange areas. Disease results when local defenses are overcome and inflammatory cells are recruited to eradicate the infection.

PULMONARY DEFENSE MECHANISMS

Pulmonary defense mechanisms are of two types (Reynolds 1994): resident defenses, such as airway architecture and mucociliary clearance, which are constantly operative, and recruited defenses, which augment the resident defenses when the host detects danger and result in inflammation with resulting disease.

Resident defenses

AIRWAY ARCHITECTURE

Movements of the glottis and epiglottis during swallowing and the cough reflex are important barriers to bacterial invasion of the airway, especially by organisms aspirated from the alimentary tract.

During nose breathing, particles larger than 5 μm are efficiently removed by impaction on the walls of the nose and nasopharynx as a result of airflow rendered turbulent by the nasal turbinates and the configuration of the nasopharynx and oropharynx. Sedimentation is the main mechanism of deposition of particles, such as bacteria in the size range 5–0.6 μm, and takes place in parts of the lung in which airflow is slow, i.e. between

the fifth bronchial division and the terminal lung units. Invasion of the lung by sedimented particles is prevented by the combination of an efficient epithelial barrier, mucociliary clearance, and phagocytic mechanisms.

THE EPITHELIAL BARRIER

The respiratory tract, from the nose to the respiratory bronchiole, is lined by ciliated, pseudostratified, columnar cells interspersed with occasional mucus-secreting cells (see Figure 1). The remainder is lined by nonciliated epithelium including (1) a small zone of stratified epithelium below the pharyngeal fornix and (2) nonkeratinizing squamous epithelium in the oropharynx, the anterior surface of the epiglottis and the upper half of its posterior surface, the upper half of the aryepiglottic folds, and the vocal cords. Tight junctions between epithelial cells provide an efficient barrier to bacterial penetration. This epithelium is continually replenished; if damaged, fully differentiated ciliated cells are replaced within 2–6 weeks, though basal cells continue to protect the basement membrane.

MUCOCILIARY CLEARANCE

Throughout the airway mucus-secreting cells secrete a blanket of mucus that is propelled along by ciliary action towards the larynx where it is coughed up or swallowed. Inhaled bacteria adhere to mucus and are conveyed along this mucociliary escalator (Figure 2). Efficient mucociliary transport of inhaled foreign bodies depends on coordinated ciliary beating, the depth and constituents of the periciliary fluid that lies beneath the blanket of mucus, and the rheological qualities of the mucus. Viscid mucus, such as that in cystic fibrosis, is difficult for the cilia to clear. Cilia beat at 12–17 Hz, but the frequency is slightly lower in more peripheral airways. In normal airways, clearance times of inhaled aerosols are 30 min from the lobar bronchi, 4–6 h from 1–5-mm airways, and 1 day to several months or more, depending on the substance inhaled, from airways distal to the terminal bronchioles. Clearly, disruption of mucociliary clearance leads to stasis of infected mucus and potentially to disease.

SOLUBLE FACTORS IN AIRWAY SECRETIONS

Mucus contains many factors that enhance the clearance of microorganisms from the airway; most of these are plasma proteins and include α_1-antitrypsin, a low-molecular-weight chymotrypsin inhibitor. Neutral protease and elastase are secreted by polymorphonuclear leukocytes and alveolar macrophages. α_1-Antitrypsin deficiency is associated with chronic pulmonary disease, probably because of failure to inhibit the neutrophil products during recurrent inflammatory responses to lung infection.

Lysozyme is secreted by neutrophils and found in most mucosal secretions, where it is directly active against some bacteria. Lactoferrin is secreted by mucosal epithelial cells and neutrophils. Like transferrin, it has a high affinity for iron and inhibits bacterial replication within the airway by restricting iron availability.

Surfactant is secreted by pneumocytes within alveoli and has the vital function of reducing surface tension in gas exchange areas and keeping these patent. Surfactant proteins A and D are significant defense molecules present in alveolar fluid that agglutinate and opsonize a

wide range of bacteria and fungi (Lawson and Reid 2000).

Complement

Many of the components of the complement system are present at very low levels in normal bronchial secretions. They are probably derived directly from serum, but alveolar macrophages also secrete a number of the components. In terms of defense against bacteria, complement has two broad functions. Deposition of C3b on bacteria ultimately results in their recognition by macrophage CR1, CR3, and CR4 receptors, and then phagocytosis. Additionally, there is probably sufficient C5 to initiate bacterial lysis by the terminal membrane attack complex. Complement concentrations rise dramatically during periods of lung damage, e.g. during serious infection of the lung, when airways are relatively leaky for serum proteins.

Immunoglobulins

Immunoglobulins IgA, IgG, IgM, and IgE, including specific antibody, can be recovered from respiratory tract secretions (Lipscomb et al. 1995). IgM is found in lung washings in only very low concentrations.

Secretory IgA (sIgA) is synthesized by lymphoid cells beneath the basement membrane, predominantly in the upper and middle portions of the respiratory tract. Whereas IgA is the predominant immunoglobulin in the upper airways, lower-airway secretions more resemble serum in that the IgG to IgA ratio is much higher. The major function of sIgA is complement-independent neutralization of respiratory viruses. It also opsonizes organisms for phagocytosis by macrophages, but it does not contribute to polymorph opsonization; nor does it activate complement. Secretory IgA interacts with lysozyme and complement to augment their bactericidal activity, mediates bacterial adherence to mucus, and inhibits bacterial adherence to epithelial surfaces. Once challenged by a given agent, the host produces sIgA in response to homologous challenge. However, the period of immune protection is relatively short in contrast to serum IgG and booster responses are variable after later challenge. Certain bacteria, notably *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, secrete IgA proteases capable of inactivating mucosal IgA and other activities.

IgG gains access to the airways by transudation from the circulation, but it can be produced locally in the lung. It efficiently agglutinates bacteria, mediates bacterial opsonization for macrophages and neutrophils, neutralizes bacterial exotoxins, and activates complement. After a primary challenge, specific antibody is released into blood from lung-associated lymph nodes and transudes into the airway. Subsequently, memory B cells traffic to the lung and produce specific IgG in response to further specific challenge (Bice et al. 1991).

ALVEOLAR MACROPHAGES

Alveolar macrophages are responsible for noninflammatory clearance of microorganisms, including those that sediment in the most distal airways beyond mucociliary clearance (Gordon and Read 2002). They comprise about 80–90 percent of the cell population of fluid obtained by bronchoalveolar lavage. Four populations of pulmonary macrophages can be distinguished:

1. alveolar macrophages
2. interstitial macrophages
3. dendritic macrophages and
4. intravascular macrophages.

Pulmonary macrophages are derived from peripheral blood monocytes; they differentiate after chemotaxis to pulmonary tissue and can replicate in the lung. Alveolar macrophages reside within the airspace, whereas interstitial macrophages are located in the lung connective tissues. Although alveolar and interstitial macrophages both undertake Fc receptor-dependent phagocytosis, they differ in their other functions. Alveolar macrophages are capable of Fc receptor-independent phagocytosis and the production of cytokines, such as tumor necrosis factor α (TNF-α) and interferons α and β, which are released in order to recruit an inflammatory response. Production of oxygen radicals is greatest in alveolar macrophages. Interstitial macrophages are adapted for antigen presentation (Lohmann-Mathes et al. 1994), whereas dendritic cells are predominantly nonphagocytic and specialized for antigen presentation. Macrophages in the vascular compartment are located on the capillary endothelium. They are highly phagocytic and probably remove foreign material that enters the lung via the bloodstream.

Alveolar macrophages possess three classes of surface receptor that facilitate phagocytosis of bacteria. The Fc receptor, of which there are four subclasses with differing affinities, are responsible for the recognition of antibody-coated bacteria. They recognize the Fc region of IgG and IgA on antibody-coated bacteria. The second are complement receptors CR1, CR3, and CR4, which recognize bacteria coated with C3b. The third are lectin-binding receptors such as the mannose-6-phosphate receptor. After phagocytosis, bacteria are enclosed in phagosomes, which ultimately acquire the characteristics of lysosomes (Gordon et al. 2000a). Bacteria are killed by a combination of products of the oxidative burst and bactericidal enzymes and other proteins.

The bactericidal activity of alveolar macrophages depends crucially on the inoculum size. Up to about 10^5 bacteria are eliminated by alveolar macrophage phagocytosis alone, whereas the killing of an inoculum of 10^6 requires a modest influx of neutrophils into the alveoli.

Inocula greater than 10^8 organisms, however, necessitate activation of local T and B lymphocytes in addition to phagocytosis by macrophages and neutrophils. Apart from the number of microorganisms, the species of the bacterium can affect the efficiency of killing by macrophages. *Staphylococcus aureus* can be killed adequately by macrophage phagocytosis alone, but *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* additionally require neutrophils to aid intrapulmonary killing. Other bacteria, such as mycobacterial species and *Legionella pneumophila*, are readily phagocytosed by macrophages but cannot be killed. Killing occurs once the macrophage has been activated by T lymphocyte-derived macrophage-activating cytokines, e.g. interleukin-1.

Alveolar macrophages, in common with other cellular components of innate immune defense, recognize pathogens via a family of Toll-like receptors and cofactors and coreceptors such as MD-2 and CD14. Following activation of these receptors by microbial ligands (e.g. lipoteichoic acid of *S. pneumoniae* or lipopolysaccharide of *H. influenzae*), there is transcriptional activation of a number of important host response genes, including those that encode cytokines and chemokines directly relevant to eradication of bacteria (Read and Wyllie 2001).

Recruited defenses

If the combined effect of mucociliary clearance, complement, and macrophage phagocytosis fails to clear an inoculum of bacteria, or if the infecting organism is particularly virulent, for example some strains of pneumococcus, polymorphonuclear neutrophils and lymphocytes are recruited to augment the host response. Neutrophils migrate from the vascular compartment into the alveolus by chemotaxis. The stimulus for chemotaxis originates within the alveolus and is due to direct generation of chemotactic factors by microorganisms entering the alveoli, and the release of chemotactic factors from alveolar macrophages after phagocytosis. Leukotriene B4 is an important chemotactic factor that also alters pulmonary capillary permeability. This, together with the secretion of TNF-α by macrophages, promotes the accumulation of neutrophils and fluid and other humoral substances in alveoli. Neutrophils kill ingested bacteria very much faster than macrophages with a combination of oxidative metabolites. This process, together with injury due to proteolytic enzymes, e.g. neutrophil elastase, contributes to consolidation of the lung.

Bronchoalveolar lavage fluid from the normal resting human lung contains predominantly macrophages but also lymphocytes (20 percent) including CD4 (helper), CD8 (suppressor), and a few B lymphocytes (Reynolds 1994). There is a complex interplay between lymphocytes, macrophages, and neutrophils in the management and termination of inflammation. Lymphocytes can regulate the activation of macrophages and subsequently coordinate the inflammatory response in a given infection. The resolution of inflammation is accompanied by neutrophil apoptosis, with subsequent consumption by macrophages. This process is conducted by inflammatory macrophages, which employ novel phagocytic recognition mechanisms that fail to provoke a macrophage proinflammatory response (Haslett 1999). Additionally, macrophages may themselves undergo apoptosis following successful phagocytic killing of some organisms, e.g. *S. pneumoniae* (Dockrell et al. 2001).

A host infected with organisms capable of intracellular survival, such as *Mycobacterium tuberculosis*, *Pneumocystis carinii*, and *Legionella pneumophila*, requires cell-mediated immunity to eradicate the infections (Sim 1998).

At the time of primary challenge, antigen is transported to lung-associated lymph nodes either contained within alveolar and dendritic macrophages or recruited neutrophils, or free in the afferent lymphatic fluid (Lipscomb et al. 1995). In the presence of lung inflammation, this process is accelerated. Within lymph nodes, antigen is reprocessed by antigen-presenting cells. Specific T and B cell clones expand and differentiate, and effector T cells and B lymphoblasts migrate out (maximally by 10–14 days), the latter to provide specific antibody locally in lung tissue. Subsequent responses to the same infecting organism are produced by immune memory B cells lodged within the lung parenchyma.

PATHOGENESIS OF BACTERIAL RESPIRATORY INFECTIONS

Disease results when the equilibrium between organisms that enter the respiratory tract and resident host defenses is disturbed. This may be due to a defect in host defenses, an overwhelming microbial challenge, or a combination of the two. A normal host may not be able to deal with the microbial load, due to the large number of organisms or because the organisms possess potent virulence determinants.

Host defense defects

HOST FACTORS THAT PERMIT INCREASED COLONIZATION OF THE UPPER RESPIRATORY TRACT

Colonization of the upper respiratory tract is probably the first step in the pathogenesis of most bacterial pulmonary infections and adherence of bacteria to epithelial cells is a key event in colonization (Woods 1994). Individuals with poor nutrition, particularly vitamin A deficiency, are more likely to have upper respiratory tract colonization. Epithelial cells from patients with severe or chronic illness appear to be particularly receptive to bacteria, especially gram-negative

organisms. This may be due to a reduction in local IgA, local fibronectin production, or a change in the glycoprotein and glycosphingolipid composition of epithelial cell surfaces.

FAILURE OF EPITHELIAL BARRIERS AND REFLEXES

Bypassing the upper respiratory tract with an endotracheal tube or by tracheostomy vastly increases the host dependence on resident host defenses of the lower respiratory tract. The distal airways in intubated patients rapidly become colonized by gram-negative bacteria including *P. aeruginosa* (Johanson et al. 1980). Failure of the swallowing reflex in patients with neurological defects permits aspiration of the commensal oropharyngeal flora and alimentary tract contents.

FAILURE OF MUCOCILIARY CLEARANCE

Ciliary dyskinesia may be due to intrinsic structural abnormalities, including defective dynein arms, defective radial spokes, microtubular transposition, and random orientation of the central tubule (Rutland and de Longh 1990). Such abnormalities can result in complications that range from relatively mild recurrent chest infections and sinusitis to severe clinical problems such as Kartagener's syndrome (sinusitis, bronchiectasis, and malrotation of viscera – *situs inversus*). Respiratory viral infection, particularly influenza, can also result in marked depletion of ciliated epithelial cells, reduced mucociliary clearance, and secondary bacterial infection, for example with *S. aureus* (Shanley 1995).

Cystic fibrosis is due to abnormalities of chloride-ion transport by glandular and ciliated epithelial cells in various tissues, resulting in viscid external secretions. In the airways, this results in inadequate mucociliary clearance, colonization by pathogens with subsequent chronic inflammation, and eventual bronchiectasis. These processes lead to virtually continuous inflammation and infection of the respiratory tract of cystic fibrosis patients from infancy onwards.

IMMUNOGLOBULIN DEFICIENCY

Patients with agammaglobulinemia and dysgammaglobulinemia produce decreased amounts of some or all of the serum immunoglobulins, notably IgG. They are susceptible to respiratory infections, including those due to encapsulated organisms, such as *S. pneumoniae* and *H. influenzae*, and others such as *Mycoplasma pneumoniae* (Buckley 1992). Chronic respiratory infection due to common variable immunodeficiency can lead to bronchiectasis. Selective IgA deficiency, particularly when associated with deficiency of IgG2, is also associated with recurrent respiratory tract infections. The IgG2 includes antibodies against capsulate organisms such as pneumococcus and *Haemophilus* spp., and also to lipoteichoic acid of *Streptococcus* spp. IgG4 deficiency is also associated with recurrent respiratory tract infection.

REDUCED PHAGOCYTIC ACTIVITY

The most common cause of failure of the phagocytic response results from iatrogenic immunosuppression. Neutropenia results in a reduced inflammatory response in the lung and an increased incidence of gram-negative bacillary and fungal infection. Macrophages can also be depleted as a result of immunosuppression, which results in pneumonia due to intracellular microorganisms, including *Legionella* spp.

DISTURBED CELLULAR IMMUNITY

Disorders of cell-mediated immunity can result from hematological malignancies, e.g. leukemia, human immunodeficiency virus (HIV) infection, or from drug therapy, e.g. steroids. The consequence for the lung is that an inflammatory response cannot be adequately recruited or controlled, and macrophages cannot be activated to kill intracellular pathogens. The reduction in CD4 (T helper cells) in acquired immune deficiency syndrome (AIDS) is associated with a variety of respiratory infections by intracellular pathogens, notably *P. carinii* and *M. tuberculosis*.

ENVIRONMENTAL INFLUENCES ON THE HOST

Tobacco smoking is the major cause of airway morbidity that leads to recurrent respiratory tract infection. Smoke reduces ciliary clearance by direct toxicity, oxidizes α_1-antitrypsin, increases mucus production, and is a chemoattractant for neutrophils and macrophages in the peripheral airways. These lead to squamous metaplasia of ciliated epithelium, goblet cell hyperplasia, and intraepithelial inflammation. The consequences are frequent cough, sputum production and intercurrent infection, particularly with *H. influenzae* and *Moraxella catarrhalis* (Floreani et al. 1994).

The effects of air pollution are far more subtle than those of smoking. Upper respiratory tract infections (coryza and nasal discharge) and lower respiratory tract infection (pneumonia and purulent sputum production) are observed more frequently in polluted urban areas (Lunn et al. 1967). High ambient pollutant levels correlate with upper respiratory infections (Ponka 1990). Pollutants, including sulfur dioxide, nitrogen dioxide, acid aerosols, and particulates, reduce mucociliary clearance, damage epithelial cells, and impair phagocytosis in vitro (Schlesinger 1990).

Bacterial virulence mechanisms

Respiratory pathogens produce a variety of virulence factors that promote infection by mechanisms that include:

- increased adherence to mucosal epithelial cells
- avoidance of mucociliary clearance

- increased nutrient acquisition
- avoidance of complement deposition and phagocytosis and
- perturbation of neutrophil and macrophage apoptosis.

Some pathogens produce factors that are directly toxic to the host, such as streptococcal hyaluronidase and *Pseudomonas* elastase, which allow expansion of the ecological niche and damage host connective tissue.

STREPTOCOCCUS PNEUMONIAE

S. pneumoniae produces a protein adhesin that binds to the *N*-acetylgalactose–galactose component of respiratory tract epithelial cell-membrane glycolipids (Krivan et al. 1988). It also produces IgA protease, which inactivates respiratory mucosal IgA. Pneumolysin, a 52.8-kDa protein, is a thiol-activated cytotoxin that shares amino acid homology with bacterial thiol-activated toxins and is released on autolysis. In experimental animals it can induce inflammation in the lungs independently of intact pneumococci (Feldman et al. 1991). Virulent pneumococci have an antiphagocytic capsule, which permits evasion of recruited neutrophils, and some capsular serotypes, e.g. serotype 3, are more virulent than others. This may be due to the relative composition of capsules, particularly their choline content (Bruyn et al. 1992). Pneumococci produce a range of other products important in pathogenesis, including pneumococcal surface protein A, autolysin, choline binding protein A (CbpA), pneumococcal surface antigen A, and neuraminidase (Jedrzejas 2001). Toxic products of *S. pneumoniae* also include hydrogen peroxide (Duane et al. 1993). The cell-wall lipoteichoic acid of *S. pneumoniae* is potently pro-inflammatory in the lung by activation of the alternative complement pathway and, like lipopolysaccharide (LPS), it elicits production of interleukin-1 (IL-1) and TNF-α (Tuomanen et al. 1995). The quantity of strain cell-wall lipoteichoic acid and capsular polysaccharide has been correlated with virulence (Weiser et al. 1996). *S. pneumoniae* expresses a C3-binding protein that elicits interleukin-8 secretion by pulmonary epithelial cells (Madsen et al. 2000), and CbpA also induces chemokine release from these cells (Murdoch et al. 2002). The complete genome sequence of *S. pneumoniae* has been published and contains 2236 predicted coding regions. Approximately 5 percent of the genome is composed of insertion sequences and there are approximately 70 predicted surface proteins (Tettelin et al. 2001).

HAEMOPHILUS INFLUENZAE

H. influenzae possesses fimbriaethat are structurally and serologically related to the P and mannose-sensitive fimbriae of *Escherichia coli* and promote adherence to respiratory epithelium and mucin. *H. influenzae* also appears to bind specifically to GalNAcβ1-4Gal sequences of human lung glycolipids. The organism may also secrete a soluble toxin that reduces ciliary beating and so promotes avoidance of mucociliary clearance (Wilson 1988). Lipo-oligosaccharide of *H. influenzae* is toxic to human respiratory tract epithelium. This organism also secretes IgA protease, which contributes to virulence (Vitovski et al. 2002).

BORDETELLA PERTUSSIS

B. pertussis produces several adhesins including a filamentous hemagglutinin (220 kDa), fimbriae, and an array of toxins, including pertussis toxin (105 kDa), which binds to respiratory tract ciliated cells and macrophages and is clearly important in airway colonization. Release of filamentous hemagglutinin from the surface of individual bacteria within adherent microcolonies facilitates dispersal of the organism through the respiratory tract (Coutte et al. 2003). Pertussis toxin also causes epithelial cell cytotoxicity by increasing host cell cyclic adenosine monophosphate (cAMP) levels (Masure 1992), an action broadly similar to cholera toxin. Tracheal cytotoxin is a peptidoglycan fragment toxic for ciliated cells that directly induces inflammation in animal models (Wilson et al. 1991). *B. pertussis* can survive in human phagocytes by inhibiting phagosome–lysosome fusion, but it does not inhibit the respiratory burst (Steed et al. 1992).

PSEUDOMONAS AERUGINOSA

P. aeruginosa produces fimbrial and nonfimbrial adhesins that mediate binding to epithelial cell gangliosides after its sialic acid residues have been removed by neuraminidase. It also produces a number of toxins, including exotoxin A, which damages respiratory epithelial tissue and inhibits phagocytosis (Coburn 1992), and a number of elastases that act together to damage epithelial cells and blood vessel walls (Galloway 1991). *P. aeruginosa* directly activates NF-kappaB, which in turn activates MUC2 mucin transcription in epithelial cells (Li et al. 1998). A membrane glycolipid of *P. aeruginosa*, rhamnolipid, can reduce ciliary beating and mucociliary clearance (Read et al. 1992), and secreted pigments, including pyocyanin and 1-hydroxyphenazine, also reduce ciliary beating (Wilson 1988). Alginate, which forms a viscous gel around bacteria and gives them a mucoid appearance, functions as an adhesin and prevents phagocytosis. Alginate also appears to contribute to biofilm formation on epithelial surfaces (Nivens et al. 2001), a phenomenon that appears to be regulated by quorum-sensing genes (Davies et al. 1998).

LEGIONELLA PNEUMOPHILA

L. pneumophila appears to survive macrophage phagocytosis and kill human macrophages. It has a 24-kDa outer-membrane macrophage invasion protein that allows invasion of macrophages in the absence of opsonization, but this does not appear to improve intracellular survival once the organism is endocytosed. The

bacterium enters macrophages by coiling phagocytosis (a form of phagocytosis in which the cell envelops the organism by coiling its pseudopodia around it) and then resides within a unique phagosome, which does not become highly acidic. Therein, legionella express stationary-phase proteins that encourage intracellular survival and transmission to new cells (Swanson and Hammer 2000). Several bacterial enzymes, including acid phosphatase, phospholipase C, protein kinases, and superoxide dismutase, potentially enhance intracellular survival. *L. pneumophila* proteases cause lung damage and secretes a metalloproteinase similar to *P. aeruginosa* elastase (Dowling et al., 1992). Adaption and replication of *L. pneumophila* in vivo are enhanced by phase variation of expression of LPS (Luneberg et al., 1998). A 22-kb DNA locus contains at least 16 genes involved in macrophage killing (Segal et al. 1998).

RESPIRATORY TRACT COMMENSALS

The anterior nares are colonized by staphylococci, micrococci, and miscellaneous *Corynebacterium* spp., but the paranasal sinuses are normally sterile.

In the mouth, anaerobes colonize periodontal areas and a variety of other organisms including 'viridans' streptococci (e.g. *Streptococcus mitis*, *Streptococcus sanguis*), *Haemophilus* spp., *Neisseria* spp., and diphtheroids are present in saliva. The practical consequence is that sputum can be heavily contaminated and make laboratory interpretation very difficult.

The flora of the oronasopharynx is much more complex; it may be colonized by *Streptococcus* spp., *Neisseria* spp., coliform bacteria, *Bacteroides* spp., fusobacteria, actinomycetes, and yeasts. From time to time, however, individuals may be colonized by one or more pathogens, such as β-hemolytic streptococci, *S. pneumoniae*, *H. influenzae*, *N. meningitidis*, and *M. catarrhalis*. Periods of asymptomatic colonization may be very short or may last for several months, and although the colonization is asymptomatic, it is generally accepted that stable residence at this site is a prerequisite for invasive disease by such organisms as *H. influenzae*, *S. pneumoniae*, and *N. meningitidis*. Point-prevalence studies in communities indicate the relative prevalence of these pathogens in the nasopharynx of colonized individuals (Table 1).

A number of exogenous factors may disturb the ecology of the mouth and nasopharynx. Antibiotics can suppress oral bacteria and allow yeasts to proliferate and thrush to occur. Smoking and passive smoking increase the prevalence of colonization with pathogens, including *N. meningitidis* (Caugant et al. 1994).

The upper respiratory tract is colonized by an abundant resident microbial flora that varies as a result of changing endogenous and exogenous conditions. Below the larynx, the lower respiratory tract is sterile in normal individuals because inhaled organisms are rapidly removed by clearance mechanisms.

INFECTIONS OF THE UPPER RESPIRATORY TRACT

Infections of the oronasopharynx

SINUSITIS

The paranasal sinuses are normally sterile. Bacteria recovered by sinus puncture before treatment of acute community-acquired sinusitis include *S. pneumoniae*, *H. influenzae*, anaerobes, *Streptococcus* spp., *M. catarrhalis*, and *S. aureus*. In chronic sinusitis, bacteriological cultures are more exotic and polymicrobial than in acute sinusitis and may include anaerobes and *Pseudomonas* spp. (van Cauwenberge et al. 1993). Conservative management of acute sinusitis involves use of appropriate antibiotics such as ampicillin, amoxycillin, trimethoprim–sulfamethoxazole, cefaclor, cefuroxime axetil, amoxycillin–clavulanate, and loracarbef (Gwaltney et al. 1992). An alternative strategy is immediate sinus puncture, which may permit more rapid resolution and provide material for the determination of antimicrobial sensitivities. Chronic disease should prompt allergic and immunological investigation and prolonged therapy, including antibiotics for anaerobic infection. Ultimately, chronic disease may require surgery to establish free drainage.

OTITIS MEDIA

Upper respiratory tract infections, often viral, are most commonly responsible for the events that lead to otitis media. Such infections impair the function of the eustachian tube, creating a negative pressure and transudation into the middle ear. Bacterial contamination results by reflux from the oropharynx, and this leads to further accumulation of fluid and pus.

Table 1 *Point prevalence of nasopharyngeal carriage of pathogens*

	Prevalence (%)
Nontypable *Haemophilus influenzae*	25–48 (Turk 1984)
Haemophilus influenzae type b (prevaccine era)	2–4 (Moxon 1986)
Streptococcus pneumoniae	60–100 (Austrian 1986)
Neisseria meningitidis	5–10 (Broome 1986)

The four stages of otitis media are:

1. Myringitis – inflammation of the tympanic membrane
2. Acute suppurative otitis media, which denotes a middle ear infection behind the reddened tympanic membrane
3. Secretory (serous) otitis media, which refers to chronic middle ear effusion behind an intact tympanic membrane with acute signs and symptoms and
4. Chronic suppurative otitis media – a chronic discharge from the middle ear through a perforation of the tympanic membrane. Chronic disease can lead to loss of aeration of the middle ear cleft, loss of hearing, and speech retardation during infancy.

Otitis media primarily affects children but can lead to lifelong sequelae. In acute otitis media the major organisms are *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis*. These organisms can also be recovered in chronic otitis media but in addition, *S. aureus*, *E. coli*, *K. pneumoniae*, *P. aeruginosa*, and anaerobic bacteria can all be present (Brook and Van de Heyning 1994). Empirical therapy may be given in most cases, including the aminopenicillins and second-generation cephalosporins and aminopenicillins in combination with β-lactamase inhibitors where β-lactamase producing organisms are present. About half the patients recover within 10 days with appropriate therapy, whereas most of the remainder have a residual exudate that resolves over 3 months. About 5 percent develop secretory otitis media. A meta-analysis has suggested that 5 days of short-acting antibiotic use is effective treatment for uncomplicated otitis media in children (Kozyrskyj et al. 1998).

Chronic otitis media requires surgical correction, drainage, and treatment for anaerobic bacteria with agents such as aminopenicillins plus β-lactamase inhibitors. In such cases, the microbiological flora should always be determined to rule out the presence of anaerobes or *Pseudomonas* spp.

RHINOSCLEROMA

This is a chronic granulomatous disease of the nose found in eastern Europe and parts of the tropics. It leads to nasal obstruction and marked secretion with postnasal drip. It is due to *K. pneumoniae* subsp. *rhinoscleromatis* (see Citrobacter, Klebsiella, Enterobacter, Serratia and other enterobacteriaceae).

Infections of the perioral and peripharyngeal spaces

Infections of oral soft tissues are uncommon and caused by endogenous oral bacteria including oral anaerobes. Such infections can lead to pain and swelling of the sublingual and submandibular space (Vincent's angina) and also collections within the lateral pharyngeal space. An extreme form of this is the rare Lemierre's syndrome, which consists of oropharyngeal infection and anaerobic bacteremia and septic thrombophlebitis of the jugular vein, with embolization to the lungs and other areas. *Fusobacterium necrophorum* is usually the cause and prolonged treatment with parenteral benzylpenicillin and metronidazole is necessary.

Peritonsillar abscess can occur in patients with recurrent tonsillitis or inadequately treated pharyngotonsillitis. Bacteria that are recovered include *Streptococcus pyogenes*, *Streptococcus milleri*, *H. influenzae*, and viridans streptococci. Anaerobes, including *F. necrophorum*, *Prevotella* spp., and *Peptostreptococcus* spp., can also be isolated from peritonsillar abscesses. The clinical features are high fever, intense pain in the throat, voice change, and occasionally airway obstruction (Jousimies-Somer et al. 1993). Treatment with needle aspiration and oral penicillin is sufficient for most patients with peritonsillar abscesses (Maharaj et al. 1991). When incipient airway obstruction is present, this is best treated by incision and drainage.

Laryngotracheal infections

Most laryngitis is due to virus infection, but *M. catarrhalis* and *H. influenzae* may be recovered from such patients and some symptoms of laryngitis can be improved with oral erythromycin (Schalen et al. 1992). Tracheitis is usually due to viruses, including respiratory syncytial virus. Bacterial pathogens associated with tracheitis include *H. influenzae*, *S. aureus*, and *Streptococcus* spp., including *S. pneumoniae*.

PNEUMONIA

This is a general term for disease that includes consolidation of the lung parenchyma. There is acute inflammation in the gas-exchanging areas of the lung (pneumonitis), with a polymorphonuclear leukocyte exudate in and around the alveoli and terminal and respiratory bronchioles.

The most useful clinical classification of pneumonia divides cases into community-acquired and nosocomial. Other considerations include whether the pneumonia results from aspiration or follows from an acute viral infection, is acquired in specific geographical settings, or occurs in the context of immunosuppression, including AIDS.

Community-acquired pneumonia

The true incidence of community-acquired pneumonia is not easy to determine, but approximately one per 1 000 of the population is admitted to hospital with pneumonia annually in the UK (Woodhead et al. 1987). In the USA it is estimated that there are 2–3 million episodes of pneumonia per annum (an attack rate of 12 per 1 000 persons per year). Each year the bacterial

pneumonias account for over half a million hospital admissions of patients aged 15 years or older in the USA (Pennington 1994a) and 45 000 deaths (Pinner et al. 1996; Marston et al. 1997). Pneumonia is substantially more common in the winter and affects more males than females (ratio 2–3:1). It is more common amongst older persons; the annual incidence of pneumonia that requires hospitalization of those older than 75 years is 11.6 cases per 1 000; for those aged 35–44 years it is 0.54 cases per 1 000 persons (Marrie 1994).

The symptoms include cough, sputum, dyspnea, and pleuritic pain. Classically the sputum is rusty-colored in pneumococcal pneumonia but is usually mucoid, scanty, or absent, especially at an early stage, and in mycoplasma and legionella infections it may be absent. Extrapulmonary symptoms occasionally predominate and patients may present with severe headache, confusion, and myalgia. Until recently, cases in which these symptoms have predominated have been described as 'atypical pneumonia' and therefore pathognomonic of mycoplasma, coxiella, and legionella infection. It is now accepted that atypical presentations may be seen with pneumococcal pneumonia and the distinction is regarded as unhelpful.

Mortality due to community-acquired pneumonia was markedly decreased by the introduction of antibiotics. In the antibiotic era, mortality from ambulatory pneumonia has been of the order of 1 percent (Woodhead et al. 1987). Mortality in hospitalized patients is about 13–15 percent (Austrian and Gold 1964; Macfarlane et al., 1982). In patients who need intensive therapy, mortality ranges from 22 to 54 percent (Woodhead et al. 1985; Torres et al., 1991). The outcome for patients admitted to hospital with pneumonia can be greatly modified by prompt antibiotic therapy. In a large multicenter study, none of the patients who died of pneumococcal, staphylococcal, or *M. pneumoniae* pneumonia had received appropriate antibiotics before hospital admission (British Thoracic Society 1987). A number of clinical and laboratory features of community-acquired pneumonia are associated with increased mortality (Table 2). Three independent studies have shown a 21-fold increase in the risk of death or the need for intensive therapy when two or more of the following factors are present:

- respiratory rate greater than 30/min
- diastolic blood pressure below 60 mmHg
- serum urea above 7 mmol/l

(British Thoracic Society 1987; Farr et al. 1991; Karalus et al. 1991).

Fine and colleagues have designed a scoring system that enables physicians to identify patients with a low risk of death within 30 days (Fine et al. 1997) and to stratify patients by severity of illness.

Table 2 *Clinical and laboratory features of community-acquired pneumonia associated with increased risk of death*

Clinical features	Laboratory features
Respiratory rate >30[a]	Urea >7 mmol/l[a]
Diastolic BP <60[a] mmHg	Serum albumin <35 g/l
Age >60 years	Hypoxemia Po_2 <8 kpa
Underlying disease	Leukopenia WBC <4 $\times$ 10^9/l
Confusion	Leukocytosis WBC >20 $\times$ 10^9/l
Atrial fibrillation	Bacteremia
Multilobar involvement	

a) Twenty-one-fold increase in risk of death or requirement of admission to an intensive therapy unit if two or three of these factors are present. Data from Farr et al. (1991); Karalus et al. (1991).

Community-treated pneumonia

Accurate epidemiological data for community-treated pneumonia are difficult to obtain. Results of three large studies in which pathogens were identified in 55–67 percent of hospitalized patients are summarized in Table 3. The predominant organisms are *S. pneumoniae*, which is by far the most common bacterial cause, *M. pneumoniae*, and viruses. These series record a preponderance of bacterial causes in hospitalized patients, but it has been estimated that at least half of nonhospitalized cases are due to viruses or mycoplasma (Pennington 1994a).

STREPTOCOCCUS PNEUMONIAE

Epidemiology

S. pneumoniae is frequently isolated from the nasopharynx of asymptomatic individuals (point prevalence 60–100 percent). The American serotyping system assigns serotype numbers in sequence. There are now in excess of 90 serotypes (see Streptococci and lactobacilli). The lower-numbered serotypes are most frequently implicated in pneumococcal diseases. In Papua New Guinea, which has a high rate of pneumococcal disease, serotypes 2, 3, 5, 8, and 14 infrequently colonize the nasopharynx but are likely to cause invasive disease. Other serotypes are commonly carried by the population and cause disease in children, but not as frequently in adults (serotypes 6, 19F, and 23F). The remaining serotypes are carried relatively rarely in the nasopharynx and do not cause disease (Montgomery et al. 1990).

A high incidence of pneumococcal bacteremia occurs in infants under 2 years of age. The incidence is low in teenage children and young adults, but increases again in males and females in their seventies. The incidence of pneumococcal disease in immunocompetent young adults is five per 100 000; the incidence of pneumococcal bacteremia is 1 000 per 100 000 patients with AIDS (Redd et al. 1990). Certain occupational groups, including military recruits, have higher annual rates of infection but the highest recorded incidence is in South African gold miners (Farr and Mandell 1994). Cigarette

Table 3 *Microbial causes of community-acquired pneumonia*

No. of patients	Location	Year of study	Microbial causes (%)	Ref.
236	Nottingham, UK	1984–85	*S. pneumoniae* (36), Viral (13), *H. influenzae* (10), GNB (1.5), *S. aureus* (1), Unknown (45)	Woodhead et al. 1987

GNB, gram-negative bacilli.

smoking is a strong independent risk factor for invasive pneumococcal disease in immunocompetent non-elderly adults (Nuorti et al. 2000).

Pathogenesis

The first step in the pathogenesis of pneumococcal disease is believed to be nasopharyngeal colonization. The average duration of carriage is about 6 weeks in adults, but some individuals may carry a strain for more than a year. Most infections occur during the first week of carriage, while sensitization and production of IgG proceed (Musher et al. 1990). People who have antibody against pneumococcal surface protein A appear to be protected against experimental nasopharyngeal carriage (McCool et al. 2002). In normal individuals, with intact mucociliary clearance, there is a much lower risk of pneumococcal disease once colonization is established in comparison with those who have pre-existing pulmonary disease or immunosuppression. However, viral respiratory infections, particularly due to influenza virus, predispose even more individuals to pneumonia. Malnourished individuals, e.g. alcoholics and residents of nursing homes, and those with chronic liver or kidney disease, cancer, or diabetes mellitus, are also vulnerable to invasive disease. Splenectomy renders individuals vulnerable to catastrophic pneumococcal bacteremia.

Highly specific enzyme-linked immunosorbent assay (ELISA) techniques have shown that most healthy young adults lack antibody to the majority of serotype-specific capsular polysaccharides (Musher 1992). Invasive pneumococcal infection probably occurs only in individuals who are deficient of serotype-specific antibody to the capsular polysaccharide of their colonizing serotype.

Clinical features

Pneumococcal pneumonia usually develops over several days with cough and sputum production, dyspnea, pleuritic chest pain, weakness, malaise, and often myalgia. Occasionally a dramatic rigor may be the first symptom; this hyperacute presentation is more common in otherwise healthy young adults. In older patients the presentation is typically more insidious with minimal cough and absence of fever; confusion and hypothermia are often presenting features in this group. Physical examination may reveal evidence of consolidation and chest radiograph commonly reveals an area of infiltration of less than a whole segment (Figure 3), and several areas may be involved (Ort et al. 1983).

Laboratory findings

Most patients have a polymorphonuclear leukocytosis; leukopenia ($<4 \times 10^9$/l) is a poor prognostic indicator. There may be hyperbilirubinemia and elevated liver enzymes.

Identification by Gram stain or culture of pneumococci in appropriate specimens remains the principal microbiological investigation. Examination of sputum requires specimens with at least 15–25 white blood cells

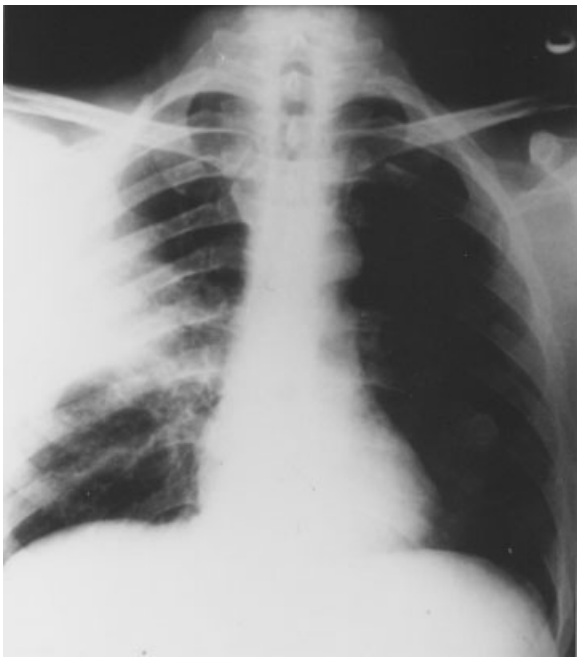

Figure 3 *Lobar consolidation in a male, age 25 years, with pneumococcal pneumonia*

and fewer than ten epithelial cells in a standard microscopic field. If lanceolate-shaped gram-positive cocci (i.e. pneumococci) are seen with more than ten cocci per oil immersion field (×100), the likelihood of culture of pneumococci in the sputum is about 60 percent and the specificity about 85 percent (Rein et al. 1978). The presence of pneumococci can be confirmed by the capsule swelling (quellung) reaction with polyvalent pneumococcal antiserum, but in practice this is rarely used. The success of culture depends on sputum quality – if saliva is present, viridans streptococci may outnumber the pneumococci. Transtracheal aspiration and transcutaneous aspiration are more sensitive but are of value only as research tools.

Pneumococcal polysaccharides can be identified rapidly in sputum, blood, or urine, but these investigations have poor sensitivity and specificity. Countercurrent immunoelectrophoresis (CIE) is positive in approximately 50 percent of patients with nonbacteremic pneumococcal pneumonia when performed on urine and serum, and in 50 percent of bacteremic patients when performed only on serum. Sputum CIE is positive in approximately 75 percent of pneumonia patients with positive pneumococcal culture and remains positive after antibiotic therapy. Latex agglutination, coagglutination and ELISA are as reliable as CIE. A pneumolysin-based ploymerase chain reaction (PCR) assay of whole blood, buffy coat, or plasma has comparable sensitivity and specificity to other antigen tests and remains positive after antimicrobial therapy (Michelow et al. 2002). Clonal origin of pneumococci can be identified by multilocus sequence typing, which is a useful tool in molecular epidemiology (Meats et al. 2003).

Complications

Empyema is the most common complication of pneumococcal pneumonia. A reactive effusion can occur but is trivial; empyema is potentially more serious and is presumably due to bacteria reaching the pleural space via the lymphatics. Clinically, it is signaled by the persistence of fever and leukocytosis after 4–5 days of appropriate antibiotic therapy. Empyema is also suggested by large amounts of pleural fluid seen on the chest radiograph and can be confirmed by ultrasound. Empyema should be drained by repeated needle aspiration or a chest tube; thoracotomy is rarely necessary. Fibrinolytic agents to irrigate the plural space may be helpful. Complications of pneumococcal bacteremia such as endocarditis, pericarditis, peritonitis, and brain abscess are very uncommon in immunocompetent individuals.

Antimicrobial therapy

Penicillin has long been the mainstay of therapy of pneumococcal disease but *S. pneumoniae* has become more resistant to penicillin over recent years (Markiewicz and Tomasz 1989). Strains with intermediate resistance are now prevalent throughout the world and highly resistant isolates are common in certain geographical areas, e.g. Southern Europe, South Africa, and the Far East, where up to 70 percent of isolates are resistant (Felmingham and Gruneberg 2000). For this reason an oxacillin disk is used routinely to screen for penicillin-resistant pneumococci. Such strains are often resistant to other antibiotics, such as chloramphenicol, erythromycin, and clindamycin (Whitney et al. 2000). In practice, pneumococcal pneumonia almost always responds to penicillin or cephalosporins in high doses (Friedland and McCracken, 1994; Pallares et al., 1995), in contrast to meningitis. Organisms highly resistant to penicillin are susceptible to vancomycin. New fluoroquinolones such as moxifloxacin are active against penicillin-resistant pneumococci, but resistance to quinolone-class antibiotics is rising in some parts of the world (Chen et al. 1999).

Prevention

The 23-valent pneumococcal vaccine contains antigens from 23 serotypes of pneumococci: 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. These types account for the majority of cases of bacteremic pneumococcal infection and the vaccine produces antibody responses in approximately 85 percent of those vaccinated. It is effective in splenectomized individuals though lower antibody levels are achieved (Giebink et al. 1980) but not in children under 2 years of age. Its use is, therefore, recommended in adults with splenic dysfunction or splenectomy and other chronic diseases, including diabetes mellitus, chronic cardiopulmonary disease, renal failure, nephrotic syndrome, liver disease, and AIDS, but its use in the immunocompromised is controversial (Hirschmann and Lipsky 1994). A large case–control field study revealed a 56 percent efficacy in preventing bacteremic pneumococcal infection; efficacy in immunocompetent patients (61 percent) was higher than in immunosuppressed patients (21 percent) (Shapiro et al. 1991). In contrast, a large randomized control trial among nonimmunocompromised middle-aged and elderly people in Sweden did not demonstrate any effect on prevention of pneumonia overall or pneumococcal pneumonia in middle-aged and elderly individuals (Ortqvist et al. 1998). The vaccines are given by intramuscular or subcutaneous injection. Repeat vaccination is recommended after 3–6 years in certain individuals, e.g. splenectomized adults or children under 10 with nephrotic syndrome or hyposplenism, but local intolerance at the injection site can be a problem. Pneumococcal disease is a particular problem in the African population with AIDS (Gordon et al. 2000b), and in this population the 23-valent vaccine was shown to be ineffective in preventing pneumococcal events (French et al. 2000).

Conjugated polysaccharide vaccines containing seven, nine, and eleven separate polysaccharides possess T-cell-dependent properties and exhibit enhanced induction of B-cell memory and high levels of immunoglobulin G even in very young children (Eskola 2000). Serogroups in the 7-valent formulation (4, 6, 9, 14, 18, 19, and 23) cause 70–88 percent of invasive disease in young children in the USA and Canada, Oceania, Africa, and Europe, but less than 65 percent in Latin America and Asia (Hausdorff et al. 2000). The 7-valent pneumococcal vaccine prevents invasive pneumococcal events in children (Black et al. 2000) and is now routinely used in children from the age of 2 months in the USA (MMWR 2000).

MYCOPLASMA PNEUMONIAE

M. pneumoniae causes tracheobronchopneumonia with severe constitutional symptoms. The clinical syndrome of primary atypical pneumonia was first described by Reimann (1938). *M. pneumoniae* causes a wide spectrum of clinical disease involving the respiratory tract, skin, central nervous system, and blood-forming elements.

Epidemiology

M. pneumoniae spreads with ease in institutions such as schools, universities, and military installations. The highest incidence is during the first two decades of life; along with *C. pneumoniae*, it is a highly significant cause of community-acquired lower respiratory tract infection in children (Principi et al. 2001). The infection can occur during any season but there is generally a 4-year cycle in which 1 year of high prevalence is followed by 2 or 3 years of low incidence (Figure 4). Explosive community outbreaks of pneumonia due to *M. pneumoniae* can occur (MMWR 2001).

Pathogenesis

The organism is carried in the nasopharynx and infection is transmitted by droplets. *M. pneumoniae* binds to epithelial cells via neuraminic acid receptors and subsequently causes damage to cells locally by hydrogen peroxide production. Once the bronchial mucosa is penetrated, a local inflammatory response is initiated. Many of the disease features are a result of a complex immune response to the organism (Tuazon and Murray 1994). Repeated infections result in the generation of sensitized T lymphocytes and autoantibodies, which initiate the pneumonitis. Immune complexes may also contribute to injury of the lung, brain, and synovia and elsewhere. The host-mediated facets of the disease explain why some patients develop only upper respiratory tract symptoms, whereas others may develop pneumonitis with or without severe extrapulmonary manifestations.

Clinical features

The clinical features are at first similar to those of influenza, except that the onset of *M. pneumoniae* infection tends to be gradual over several days or a week (Clyde 1993). Constitutional symptoms initially include headache, malaise, myalgia, and pharyngitis, but rigors are uncommon. The cough, which is initially dry and dominates the disease, is the last symptom to clear. Despite antibiotics clinical relapse can occur a week after the initial response. The physical signs are often minimal and include sinus tenderness, pharyngitis without exudate, and occasionally myringitis. The chest is initially clear, but wheezing and rhonchi may develop in the second week. Although the pneumonia is usually self-limited, occasionally adult respiratory distress syndrome associated with *M. pneumoniae* may develop. Other

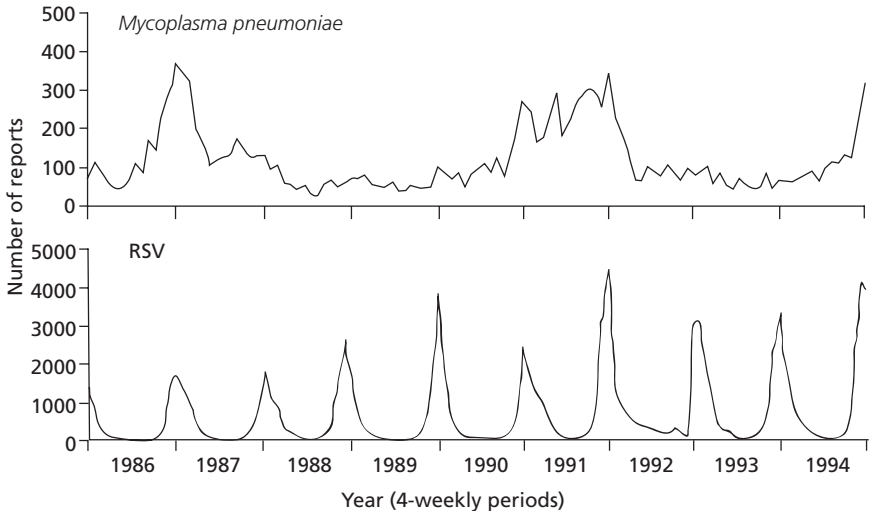

Figure 4 *Periodicity of* Mycoplasma pneumoniae *infection, in comparison with respiratory syncytial virus (RSV). (Reproduced with permission from CDSC 1995.)*

pulmonary complications are unusual (Tuazon and Murray 1994).

Extrapulmonary manifestations

Pneumonia with rash is most commonly due to *M. pneumoniae*. Stevens–Johnson syndrome in association with *M. pneumoniae* is potentially life-threatening and is probably due to the cell-mediated immune response to *M. pneumoniae*, but since the rash often develops after drug therapy, antibiotics, particularly erythromycin, may be responsible (Cherry 1993).

Hemolytic anemia characteristically occurs 2–3 weeks after the onset of illness, is usually self-limiting, and coincides with high cold agglutinin titers. It is complement-dependent and involves IgM antibody to the I antigen of red blood cells (Cherry 1993). Although hemolytic anemia is uncommon, approximately three-quarters of patients with *M. pneumoniae* pneumonia develop high titers of cold agglutinins.

Central nervous system symptoms are present in up to 70 percent of patients with *M. pneumoniae* infection treated in hospital (Koskiniemi 1993). Encephalitis is the most frequent CNS manifestation, but meningitis, myelitis, and polyradiculitis and many other symptoms, including coma, ataxia, and stroke due to cerebral infarction, have been reported. *M. pneumoniae* has not been isolated from brain tissue but has been recovered from the cerebrospinal fluid (CSF). In aseptic meningitis the CSF usually reveals a modest pleocytosis.

Laboratory findings

The white blood cell count is usually greater than 10×10^9 per liter and neutrophilia, lymphocytosis, and monocytosis can all occur, but leukopenia is rare. Routine sputum culture is negative, but *M. pneumoniae* can be grown in broth media in long-term cultures.

A useful bedside test detects the presence of cold agglutinins. A few drops of blood are placed into a citrate tube and placed in a refrigerator for a few minutes. If cold agglutinins are present, then agglutination of red cells will be seen. The IgM cold agglutinins first appear 7–9 days after infection with a peak after 4–6 weeks.

The mainstay of diagnosis is serological. A four-fold increase in complement fixation titer is diagnostic. Unfortunately serology is frequently negative during the acute phase; even laboratory assay for cold hemagglutinins, the first acute-phase marker, is positive in only about 50 percent of acutely ill patients. Some centers offer PCR for *M. pneumoniae*, a technique that is improving in value (Loen et al. 2002). The combination of PCR detection within nasopharyngeal samples together with ELISA-based IgM detection greatly enhances diagnostic yield in children (Ferwerda et al. 2001).

Antimicrobial therapy

The mainstays of treatment for *M. pneumoniae* infection are erythromycin and tetracycline. Recovery with erythromycin is quite slow. Newer macrolides such as azithromycin and clarithromycin are better tolerated and have equivalent activity in vitro. Newer fluoroquinolones are also active against *M. pneumoniae* (Bébéar et al. 1993).

Prevention

Killed and inactivated vaccines do not evoke effective serum or local respiratory tract immune responses (Tuazon and Murray 1994). Future vaccines may be based on recently discovered peptide adhesins.

LEGIONELLA PNEUMOPHILA

This organism is named after an epidemic of pneumonia in legionnaires who attended the American Legion Convention in Philadelphia in the late summer of 1976 (Fraser et al. 1977). Among the 4500 persons attending, 192 cases were observed and 29 proved fatal. The syndrome was characterized by nonproductive cough, pulse temperature dissociation, abnormalities of liver function, diarrhea, hyponatremia, hypophosphatemia, myalgia, confusion, and multiple rigors. The condition became known as legionnaires' disease. A previously unknown pleomorphic gram-negative bacillus was isolated from four of the original patients and named *L. pneumophila*. Some 3 years later an acute, short-lived, febrile illness consisting of myalgia but not pneumonia that affected staff and visitors at the County Health Department at Pontiac, Michigan, was shown to be due to *L. pneumophila*. It had a shorter incubation period and there were no deaths (Broome and Fraser 1979). Subsequently devised serological techniques implicated *Legionella* spp. in pneumonia not only in outbreaks associated with the water facilities of large buildings such as hospitals and hotels but also with sporadic community-acquired infections. Legionella are aerobic, fastidious, gram-negative bacilli, of which 34 species have been characterized (see Legionella).

Rarely, infections may be caused by *L. micdadei*, *L. longbeachae*, *L. dumoffii*, *L. bozemanii*, and other species (Edelstein and Meyer 1994).

Pathogenesis

Infection results from inhalation of *Legionella*-contaminated aerosols, e.g., disseminated by cooling towers, humidifiers, respiratory therapy equipment, showerheads, and cooling sprays. *L. pneumophila* is phagocytosed by macrophages but they fail to kill the organism. In macrophages infected in vitro, legionella can multiply between 100 and 1 000 times in 48–72 h (Yamamoto et al. 1994). Defense against the infection, therefore,

crucially depends on cell-mediated immunity, as illustrated by the susceptibility to legionellosis of patients in whom such immunity is deficient; those with neutropenia do not appear to be susceptible.

Epidemiology

Legionella spp. survive in water for prolonged periods, as intracellular parasites of free-living protozoa (Fields et al. 2002). Although human infection occurs sporadically in the community (Macfarlane et al. 1982), outbreaks are dramatic and associated with water facilities. Of the 129 cases of legionnaires' disease reported in England and Wales in 1993, 51 percent were associated with travel, mainly to Spain, but also to Greece, Turkey, the USA, and within the UK; six were nosocomial and the remainder were sporadic community cases (Joseph et al. 1994a). Outbreaks have occurred in the vicinity of cooling towers (Broome and Fraser 1979), a power station (Morton et al. 1986), and, notably, Broadcasting House, London, in 1988. The role of air-conditioning equipment was demonstrated in Memphis in 1978 (Dondero et al. 1980) and by a large hospital outbreak in Staffordshire, UK (Editorial 1986). Showerheads and hot-water taps spread aerosols contaminated with *Legionella* (Bolling et al. 1985). This has caused outbreaks in hospitals and is the probable cause of disease in holidaymakers returning from Mediterranean resorts. Contaminated showerheads and tap water led to a prolonged and disastrous outbreak in the VA Wadsworth Medical Center, Los Angeles, with a high rate of nosocomial *Legionella* pneumonia, particularly in immunosuppressed patients. The outbreak was terminated by changing showerheads and by hyperchlorination of potable water (Shands et al., 1985). Between 1980 and 1992, 218 cases were reported in the UK, 68 of whom died. Approximately half were sporadic, but three hospital outbreaks contributed to the majority of the remaining cases. Hospital domestic water systems were the source of infection in 19 outbreaks. The cooling tower was thought to be the source in one hospital and probably contributed to two other outbreaks in which the domestic water system was suspected to be the main source (Joseph et al. 1994b). It is considered that contamination of water only presents a risk at a threshold concentration of 10^4–10^5 cfu per liter, though low concentrations can be underestimated because of insensitive culture techniques (Leoni and Legnani 2001).

Clinical features

The majority of patients with *L. pneumophila* infection have a pneumonia virtually indistinguishable from pneumococcal pneumonia (Edelstein 1993; Stout and Yu 1997). Clinical features range from asymptomatic infection and nonpneumonic myalgia (Pontiac fever) to legionnaires' disease with severe pneumonia and extrapulmonary manifestations. After an incubation period of 2–10 days, there is a gradual onset of malaise, lethargy, fever, headache, myalgia, and weakness, with evolution of a dry nonproductive cough after 1–2 days. There may be purulent sputum, which can be bloody (Edelstein 1993). In about 25 percent of patients there may be disorientation, agitation, confusion, hallucinations, ataxia, and seizure. The systemic manifestations are probably due to several exotoxins and, possibly, endotoxins (Edelstein and Meyer 1994). Extrapulmonary manifestations include pancreatitis, peritonitis, cellulitis, myositis, and focal abscesses, and prosthetic valve endocarditis is well recognized. Pneumonia due to species other than *L. pneumophila* is clinically indistinguishable. *Legionella micdadei* infection occurs in immunosuppressed patients and causes nodular pulmonary infiltrates (Pittsburgh pneumonia) (Myerowitz et al. 1979).

Diagnosis

Nonspecific laboratory abnormalities include elevated white blood count (usually with neutrophilia), hyponatremia, elevation of alkaline phosphatase and liver transaminases, and proteinuria. The gold standard for the diagnosis of legionnaires' disease is culture of *Legionella* spp. from sputum samples on charcoal yeast extract medium (BCYE), but this is only possible in patients with productive cough. Antigen can be detected in sputum, respiratory secretions, bronchoalveolar lavage, or lung biopsy using immunofluorescence with genus-specific monoclonal antibodies, even after several days of chemotherapy (Fields et al. 2002). Techniques to detect nucleic acid, for example PCR, are of relatively low sensitivity and are practiced in very few laboratories. Urinary antigen detection has an overall sensitivity of 80 percent (Helbig et al. 2003) but detects only serogroup 1 *L. pneumophila*. Serological diagnosis can be conducted with a variety of techniques, including complement fixation and ELISA, and relies on a four-fold rise between acute and convalescent titres (which can take up to 2 months) or a single titer of $\geqslant$1:256. In culture confirmed cases, the sensitivity of serology is 70–80 percent.

Antimicrobial chemotherapy

In the legionnaires' disease outbreak in Philadelphia in 1976, the case fatality rate was highest for patients treated with cephalosporins and lowest with erythromycin. Erythromycin should be given at a dose of 2–4 g per day, initially intravenously in severely ill patients, for at least 3 weeks. Rifampicin and a fluoroquinalone should be added for patients who are critically ill. Patients usually respond to erythromycin therapy within 2–3 days.

Antimicrobial sensitivity testing is not applicable to *L. pneumophila*. Most of the β-lactam agents are active in

vitro against *L. pneumophila*. However, animal models have shown that these agents are ineffective because they do not enter macrophages sufficiently well. Therefore, the potential efficacy of new agents must be based upon their success in intracellular infection and experimental animal models. Azithromycin, clarithromycin, fluoroquinolone antibiotics, trimethoprim–sulfamethoxazole, tetracyclines including doxycycline, and rifampicin are effective in animal models (Edelstein 1993). In patients with *Legionella* who are severely ill or immunocompromised, a fluoroquinolone must be included in the chemotherapeutic regimen (Edelstein 1995).

Prevention

Person-to-person transmission of legionnaires' disease has not been observed. The most important preventive measure is to render water sources safe. Thirty to 80 percent of hospital cooling towers and water supplies are to some extent contaminated with *Legionella*, and at total viable concentrations $>10^8$ cfu/l the hazard of infection is increased (Edelstein and Meyer 1994). Chlorination, pasteurization, and heating can be used to reduce the *Legionella* burden (Muraca and Stout 1988).

The report of a single case of legionnaires' disease requires investigation to determine whether it is part of an outbreak, which involves tracing the patient's activities during the incubation period. If hospital-acquired infection is suspected, then the hospital water maintenance programme must be reviewed and a search made for associated cases, beginning with the immunosuppressed population, who are most vulnerable to infection (Saunders et al. 1994).

COXIELLA BURNETII

C. burnetii (see Rickettsia and Orienta) is the cause of Q fever, which was first described in Australia in the 1930s in abattoir workers. The organism spreads between farm animals and man by air-borne transmission, by infected milk, feces, and urine, and is probably also transmitted by tick bite. It is highly resistant to drying and in agricultural facilities contaminates dust, which can cause infection by inhalation. After an incubation period of 2–4 weeks there is abrupt onset of high fever, malaise, headache, and neck stiffness. There is dry cough and pleuritic chest pain and on examination there is usually high fever, hepatosplenomegaly, but few chest signs. Some patients develop a transient maculopapular rash, but the exanthem typical of other rickettsial infections is absent. Most illness resolves within 2 weeks but fever can persist for up to 3 months. Q fever can be complicated by extrapulmonary lesions, including endocarditis. There may be hepatitis, which is usually mild but can be severe or even fulminant. *C. burnetii* may cause blood culture-negative endocarditis many months after the primary infection.

Complement fixation and indirect fluorescent antibody tests reach a peak between 1 and 3 months after original infection. Phase 2 antibodies are raised in acute Q fever; phase 1 antibodies are prominent in patients with chronic Q fever, e.g. endocarditis.

Tetracycline or doxycycline is used to treat acutely ill patients and those with persistent symptoms. Long-term treatment with tetracycline is desirable for patients with Q fever endocarditis, but valve replacement may become necessary.

STAPHYLOCOCCUS AUREUS

Although *S. aureus* pneumonia is usually nosocomial, it accounts for a small proportion of community-acquired pneumonia, particularly during influenza epidemics and in certain patient groups, e.g. diabetics. Although 15–30 percent of adults are nasal carriers of *S. aureus*, resulting pneumonia is rare and presumably requires an underlying host defect, e.g. diabetes. Staphylococcal pneumonia is also seen in patients with right-sided endocarditis (e.g. in intravenous drug abusers) and in patients with septic thrombophlebitis or an infected vascular prosthesis (Farr et al. 1989). Patients with staphylococcal pneumonia more commonly have pleural effusions and cavitation on chest radiograph and 25 percent develop abscesses (Waldvogel 1990). Staphylococcal pneumonia secondary to septic embolization from right-sided endocarditis causes multiple small round cavitary lesions.

The appearance of clusters of staphylococci on Gram stain of sputum is diagnostic of staphylococci pneumonia. If this diagnosis is suspected after clinical assessment of a patient, sputum microscopy can rapidly confirm the diagnosis and a penicillinase-resistant penicillin can be added to the empiric antibiotic regimen. Vancomycin should be used only when pneumonia due to methicillin-resistant *S. aureus* is suspected.

HAEMOPHILUS INFLUENZAE

H. influenzae causes community-acquired pneumonia in patients with chronic bronchitis and those with impaired host defenses, such as smokers, alcoholics, or HIV infection. In the pre-Hib vaccine era, it was also a relatively common cause of pneumonia in children, particularly those aged 4 years and younger. Nontypable *H. influenzae* tends to cause mucosal infections, such as those affecting the middle ear and the airway of bronchitics. Capsulate organisms, particularly of type b, cause a significant proportion of invasive parenchymal disease, i.e. pneumonia (Smith 1994). In adults and children the illness tends to be preceded by coryza, and sudden onset of pleuritic chest pain is the predominant chest symptom (Crowe and Lavitz 1987). Microbiological diagnosis is notoriously difficult because of sputum contamination by commensal *Haemophilus* spp. and blood culture is

usually negative. β-Lactamase production by infecting strains may be very frequent in some areas (Felmingham and Gruneberg 2000). If such strains may be involved, second-generation cephalosporins should be used to treat moderately severe pneumonia.

CHLAMYDIA SPECIES

Pneumonia due to chlamydia is common. See Chlamydia.

GRAM-NEGATIVE BACILLARY PNEUMONIAS

Although gram-negative bacteria are a prominent cause of nosocomial pneumonia, they may also cause disease in the community, particularly in alcoholics, diabetics, residents of nursing homes, and patients with underlying diseases, such as malignancy and cardiac or renal failure. The upper respiratory tract becomes colonized followed by aspiration and subsequent pneumonia. The most common gram-negative causes of community pneumonia are *K. pneumoniae*, *E. coli*, *Serratia marcesens*, *Enterobacter* spp., and *Pseudomonas* spp.

K. pneumoniae classically causes pneumonia in debilitated middle-aged males, with sudden fever and rigors, dyspnea, and large volumes of bloody sputum. Often there is a necrotizing process with multiple abscess formation and dramatic lobar consolidation. The sputum contains large numbers of capsulate gram-negative bacilli and blood cultures are often positive. The infection is destructive, often is severe, and has a high mortality (Feldman et al. 1989).

E. coli is the cause of up to 3 percent of community pneumonias in American series (Eisenstadt and Crane 1994). It may result from bacteremic spread from the genitourinary and gastrointestinal tracts and is often bilateral. Other causes of community-acquired gram-negative pneumonia include *Proteus* spp. (*Morganella* and *Providencia* spp.) and *Acinetobacter baumannii*.

Pseudomonas spp. can, rarely, cause dramatic community-acquired pneumonia. *P. aeruginosa* causes pneumonia in patients admitted from nursing homes or individuals with malignancy. The disease is often necrotizing and there is diffuse bilateral consolidation on chest radiograph with occasional multiple abscesses. *Pseudomonas stutzeri* may cause disease in patients with malignancy (Noble and Overman 1994). For a discussion of pneumonia due to *Burkholderia pseudomallei*, the reader is referred to Burkholderia spp., and related genera.

STREPTOCOCCUS SPECIES

Both group A and group B streptococci may cause pneumonia, the latter particularly in elderly debilitated patients with diabetes mellitus, stroke, dementia, and malignancies, and is often associated with other organisms, particularly *S. aureus* and *S. pneumoniae*. Enterococci can cause pneumonia in elderly debilitated patients with multiple chronic problems, often with nasogastric tubes. Treatment is with high-dose penicillin or ampicillin and an aminoglycoside.

BACILLUS ANTHRACIS

Most (95 percent) natural infection by *B. anthracis* results in the cutaneous form of anthrax, but inhalation of spores can result in inhalational anthrax within 60 days of exposure (Friedlander et al. 1993). Inhalation anthrax usually begins with mild fever and malaise, myalgia, and nonproductive cough. Within 2 or 3 days there is rapid evolution of fever, acute dyspnea, cyanosis, and shock. Mediastinal and cervical lymphadenopathy may be sufficiently severe to cause stridor. The chest radiograph reveals mediastinal widening and occasionally parenchymal infiltrates. Microbiological diagnosis of inhalational anthrax is usually made by blood culture of a heavily encapsulated gram-positive bacillus or by PCR detection in tissue samples (Levine et al. 2002). Confirmation can be done by lysis by gamma phage or direct fluorescent antibody staining of cell-wall polysaccharide antigen. Treatment of cases is with ciprofloxacin 400 mg twice daily intravenously (Swartz 2001). Inhalation exposure of individuals without disease can be investigated by nasopharyngeal swabbing and culture or PCR detection. Post-exposure prophylaxis with ciprofloxacin 500 mg or doxycycline 100 mg both orally and twice daily for 60 days is recommended for persons exposed to spores (Inglesby et al. 2002).

FRANCISELLA TULARENSIS

Exposure to as few as one to ten aerosolized organisms may cause tularemia, which may present as pneumonia or in an ulcerglandular or typhoidal form. The incubation period is 1–21 days, with initial symptoms of fever, malaise, and nonproductive cough. The chest radiograph usually reveals pneumonia with or without mediastinal lymphadenopathy. The organism is difficult to culture from blood but serology is positive in 50–70 percent of cases by the second week of illness. Standard therapy is with gentamicin, streptomycin, or doxycycline.

OTHER RARE CAUSES OF BACTERIAL PNEUMONIA

N. meningitidis can cause a typical pneumonia in the absence of the classic or cutaneous rash and without evidence of meningitis or shock. The disease occurs as outbreaks in military and school dormitories (Koppes et al. 1977). The lungs may be involved in up to 20 percent of cases of brucellosis (Lulu et al. 1988) (See Brucella). *Pasteurella multocida*, which causes cellulitis after dog bites, can cause a necrotizing pneumonia, usually in patients with pre-existing respiratory disease and with history of exposure to domestic animals. *Yersinia pestis* can cause pneumonia as part of a septicemic process (see Yersinia).

THE APPROACH TO PATIENTS WITH COMMUNITY-ACQUIRED PNEUMONIA

In most patients presenting with symptoms and signs of pneumonia the likely cause is *S. pneumoniae*. Routine laboratory investigation should include sputum examination and culture, blood culture, acute and convalescent serology to detect antibodies to viruses, *Mycoplasma* spp., *Chlamydia* spp., *Legionella* spp., and *Coxiella burnetii*, urinary antigen detection, and examination of pleural fluid, if available (Carroll 2002), Yersina.

ANTIMICROBIAL THERAPY

The British, European, and American thoracic societies, and also the Infectious Disease Society of America, have each issued guidelines for the management of adult community-acquired pneumonia, and these are summarized in Table 4. Each of these guidelines is opinion-based, as the evidence available to discriminate between therapies is limited (Read 1999). All modern guidelines stratify patients by demographic and epidemiological features and include suggested therapies tailored to the likely pathogens that are seen in more complex clinical settings. The British Thoracic Society guidelines recommend the use of an aminopenicillin (e.g. amoxycillin) in patients with simple community-treated pneumonia who are ambulatory, with erythromycin recommended as an alternative choice. In view of the fact that the greatest cause of mortality is due to *S. pneumoniae*, aminopenicillins are probably adequate in the treatment of the majority of patients with mild community-acquired pneumonia treated in the UK. A problem in southern and eastern Europe, the USA, the Asia-Pacific region, and South Africa has been the emergence of penicillin-resistant pneumococci. Aminopenicillins have not been widely employed in the USA for the management of community-acquired pneumonia, largely because of the perceived frequency of atypical pathogens as microbial etiologies in this condition, and the difficulty in distinguishing, on clinical grounds alone, those patients who are infected with such pathogens. The emergence of penicillin-resistant pneumococci, especially in countries other than the UK, has led to the inclusion of fluoroquinolones as choices in first-line management, even for ambulatory patients. The treatment guidelines issued by the Infectious Diseases Society of America (IDSA) (see Table 4) recommend the use of either doxycycline, a macrolide drug, or a fluoroquinolone for first-line therapy of patients with mild ambulant (outpatient) pneumonia. While such recommendations would probably not be germane in, for example, the UK, in certain parts of the world they are certainly appropriate – the frequency of penicillin resistance in Spain varies from 50 to 70 percent. In such regions, the frequency of macrolide resistance is also high, and clinical failures with this class have been reported.

As can be seen in Table 4, the American Thoracic Society (ATS) has produced a sophisticated set of guidelines in which the likelihood of involvement of penicillin-resistant pneumococci or relatively unusual pathogens in certain patient groups is acknowledged. The ATS recommends the use of either macrolides or tetracyclines for patients who are managed as outpatients and have no pulmonary comorbidity. This approach was validated in the early 1990s (Gleason et al. 1997) in a study of 864 outpatients with community-acquired pneumonia (55.4 percent of whom yielded a positive microbiological diagnosis); 547 younger patients without comorbidity were treated; of these younger patients, 62 percent were prescribed therapy recommended by the ATS – predominantly erythromycin. There were no significant differences in medical outcome between these patients and outpatients who had been erroneously prescribed more sophisticated therapy, but their treatment was associated with a three- to four-fold lower treatment cost.

For outpatients who have pulmonary comorbidities or other risk factors for more exotic flora, including penicillin-resistant pneumococci (e.g. older age), the current ATS guidelines recommend the use of more sophisticated treatments, including oral cephalosporins or a β-lactam/β-lactamase inhibitor combination in addition to a macrolide or doxycycline. An alternative choice for this group is a fluoroquinolone with antipneumococcal activity. The ATS specifies available fluoroquinolones with such activity and ranks them in descending order of antipneumococcal potency as moxifloxacin, gatifloxacin, sparfloxacin, then levofloxacin.

This approach is also followed in the recent guidelines from the IDSA, in which a fluoroquinolone such as moxifloxacin, gatifloxacin, or levofloxacin is recommended in elderly patients or those with underlying disease (see Table 4).

HOSPITALIZED PATIENTS

Patients who require hospitalization are often in groups at risk of unusual pathogens and/or more severe disease. All guidelines recommend broader-spectrum (often combination) therapy for this group (see Table 4), but the ATS guidelines stratify inpatients further into those with or without cardiopulmonary comorbidities or other modifying factors, including nursing-home residency. It is recommended that these inpatients should receive aggressive therapy with an IV β-lactam/macrolide combination or an IV antipneumococcal fluoroquinolone given as monotherapy.

SEVERE COMMUNITY-ACQUIRED PNEUMONIA

All patients with severe community-acquired pneumonia should be managed with adequate ventilatory support and fluid resuscitation, in addition to antibiotics. This group has a high mortality and the pathogens most frequently implicated as the microbial cause include *S. pneumoniae*, *Legionella* spp., *H. influenzae*, enteric

Table 4 *Guidelines for first-line empirical management of community-acquired pneumonia*

Society	Mild ambulant pneumonia (outpatient)	Ambulant pneumonia with risk factors (outpatient)	Inpatient pneumonia (medical ward)	Severe pneumonia (intensive care unit)
European Respiratory Society (1998) (ERS Task Force Report 1998)	Aminopenicillin, or new tetracycline or newer FQ, oral streptogramins, or macrolide	Inpatients with COPD: β-lactam/β-lactamase inhibitor	IV second- or third-generation cephalosporin or IV β-lactam/β-lactamase or IV aminopenicillin and IV macrolide	Either a second- or third-generation cephalosporin and a newer FQ, or macrolide ± rifampicin
Infectious Diseases Society of America (2000) (Bartlett et al. 2000)	Doxycycline or a macrolide, or a newer FQ	Suspected drug-resistant *Streptococcus pneumoniae*, or older patients, or patients with an underlying disease: a newer FQ	A macrolide plus either an extended-spectrum cephalosporin or a β-lactam/β-lactamase inhibitor, or a newer FQ (alone)	Either an extended-spectrum cephalosporin or β-lactam/β-lactamase inhibitor, plus either a newer FQ or a macrolide
American Thoracic Society (2001)	Macrolide (azithromycin or clarithromycin) or doxycycline	With cardiopulmonary disease: β-lactam (oral cefpodoxime, cefuroxime, amoxil, co-amoxiclav) or parenteral ceftriaxone followed by oral cefpodoxime plus macrolide or doxycycline or antipneumococcal FQ monotherapy	Cardiopulmonary disease or nursing home: IV β-lactam (cefotaxime, ceftriaxone, ampicillin/sulbactam, high-dose ampicillin plus IV/PO macrolide or doxycycline or IV antipneumococcal FQ monotherapy, no modifying factors: IV azithromycin or doxycycline plus β-lactam or IV antipneumococcal FQ	No risk of *P. aeruginosa*: IV β-lactam plus IV azithromycin or fluoroquinolone. Risk of *P. aeruginosa*: IV antipseudomonal β-lactam (cefepime, imipenem, pip/tazo) plus IV ciprofloxacin or IV antipseudomonal β-lactam plus IV aminoglycoside plus IV azithromycin or IV FQ
British Thoracic Society (2001)	Amoxycillin or erythromycin	Not specified	Oral amoxycillin plus erythromycin or IV ampicillin plus IV clarithromycin or IV FQ plus IV penicillin	Co-amoxiclav or 2/3 cephalosporin plus clarithromycin ± rifampicin or FQ plus IV penicillin

COPD, chronic obstructive pulmonary disease; FQ, fluoroquinolones (include moxifloxacin, gatifloxacin, levofloxacin); IV, intravenous; PO, orally, 2/3 2nd or 3rd generation.

gram-negative bacilli, *Mycoplasma* spp., and *S. aureus*. There is a paucity of clinical trial data to support individual choices of empirical antimicrobial therapy but, in general, patients should be managed with broad-spectrum therapy: usually an IV cephalosporin with the addition of an IV macrolide. In patients for whom there is clinical or laboratory evidence leading to suspicion of *S. aureus*, IV fluocloxacillin (nafcillin) or vancomycin should be added.

Nosocomial pneumonia

Pneumonia is the second most common nosocomial infection after urinary tract infection (Horan et al. 1986), causes considerable mortality and morbidity, and increases hospital stay and its cost. The US Centers for Disease Control have published the following definition of nosocomial pneumonia:

Onset of pneumonia more than 72 h after hospital admission with lung consolidation or an infiltrate on the chest radiograph plus at least one of the following:

- Infected sputum
- Isolation of a pathogen from the blood, transtracheal aspirate, biopsy, or bronchial lavage specimen
- Isolation of a virus in respiratory secretions
- Diagnostic antibody titers or
- Histopathological evidence of pneumonia (Centers for Disease Control 1988).

According to the US National Nosocomial Infection Surveillance (NNIS) system, nosocomial pneumonia occurs at a frequency of 0.6–1.0 episodes per 100 hospitalizations and in 18 percent of postoperative patients (Horan et al. 1986; Craven et al., 1991). Intubated patients may have rates of pneumonia seven- to 21-fold higher than patients without a respiratory therapy device; the incidence of ventilator-associated pneumonia (VAP) varies from ten to 25/1 000 ventilator days (Chastre and Fagon 2002). Infection rates are twice as high in large teaching hospitals compared with smaller institutions. Factors that lead to nosocomial pneumonia include older age, chronic lung disease, depressed consciousness, mechanical ventilation, the use of H2 antagonists, frequent changes of ventilator circuits, and the winter season (Celis et al. 1988). Mortality in patients with nosocomial pneumonia is high (20–50 percent), but only about one-third of fatalities are due directly to pneumonia (Pennington 1994b).

PATHOGENESIS

Most nosocomial pneumonia results from aspiration of pathogens from the upper airways. Patients admitted to intensive care units become colonized with aerobic gram-negative bacilli within 1 week of entering hospital, and of these about 25 percent develop nosocomial pneumonia; there is a correlation between severity of illness and the likelihood of subsequent colonization with gram-negative organisms (Johanson et al. 1969). Enterobacteriaceaea probably reach the upper respiratory tract by fecal–oral transmission. However, *P. aeruginosa* and *S. aureus* probably colonize the patient from environmental sources and contamination by attending staff, fomites, or supporting equipment (Pennington 1994b). Any factors that reduce gastric acidity may lead to increased oropharyngeal colonization: these include advanced age, achlorhydria, malnutrition, and various pharmacological agents.

MICROBIAL ETIOLOGY

The majority of hospital-acquired pneumonias are caused by aerobic gram-negative bacilli; Enterobacteriaceae cause 40 percent of these pneumonias, *S. aureus* 25 percent, and *P. aeruginosa* 15 percent; *S. pneumoniae*, *H. influenzae*, fungi, viruses, and anaerobic bacteria rarely cause nosocomial pneumonia. The results of three large studies of nosocomial pneumonia are shown in Table 5. Polymicrobial infections are common. Nosocomial pneumonia that occurs during the first 4 days in hospital is usually due to one of *S. pneumoniae* and

Table 5 *Bacteriology from three nosocomial pneumonia studies*

Culture material	Sputum (%)	TTA (%)	Blood (%)
Study	Hughes et al. (1983)	Bartlett et al. (1986)	Bryan and Reynolds (1984)
Pseudmonas aeruginosa	17	9	15
Staphylococcus aureus	13	26	27
Enterobacteriaceae[a]	37	48	42
Fungi	6	ND	ND
Anaerobic bacteria	2	35	2
Streptococcus pneumoniae	<3	31	12
Haemophilus influenzae	<3	17	<4
Viruses	<3	ND	ND

ND, not done; TTA, transtracheal aspirate.

a) Includes *Klebsiella pneumoniae*, *Enterobacter* spp., *Escherichia coli*, *Serratia*, and *Proteus*.

H. influenzae. Nosocomial pneumonia occurring later than 4 days after admission is more commonly caused by hospital-acquired, aerobic gram-negative bacilli, *S. aureus*, *Legionella* spp., or, rarely, fungi. A number of host risk factors can predispose to infection with particular pathogens (reviewed by Niederman 1994). Staphylococcal pneumonia is associated with diabetes, renal failure, a recent history of influenza, and recent head injury and trauma, whereas *P. aeruginosa* is seen in malnourished patients and those on steroids or who have chronic structural lung disease or are subject to prolonged mechanical ventilation or tracheostomy. *L. pneumophila* may cause nosocomial pneumonia in hospitals with contaminated water supplies, particularly in patients immunosuppressed by treatment with steroids. Anaerobes are seen particularly in patients with gross aspiration of acid gastric contents and recent thoracoabdominal surgery. *Acinetobacter* spp. are a significant cause of nosocomial pneumonia on surgical intensive care units and are a particular problem because of multiple antibiotic resistance (Fagon et al. 1989). Viruses may contribute to nosocomial pneumonia, particularly influenza A, parainfluenza, and adenovirus (Dal Nogare 1994).

Methods for the diagnosis of nosocomial pneumonia in severely ill patients include transtracheal aspiration, bronchoscopic sampling with or without protective brush, and transcutaneous aspiration of lung material, but in many studies these have not proved superior to clinical evaluation (Pennington 1994b). In patients who are conscious, sputum production may yield gram-positive (*S. aureus*) or gram-negative bacteria. In intubated patients, aspirated respiratory secretions and blood cultures may provide a bacteriological diagnosis without the need for bronchoalveolar lavage.

TREATMENT AND PREVENTION

Appropriate therapy should include antibiotics active against *S. aureus* and gram-negative bacteria, including *P. aeruginosa*; common regimens include a third-generation cephalosporin or fluoroquinolone plus an aminoglycoside. In patients infected with *Acinetobacter* spp., imipenem and tetracycline are among the most active drugs (Vila et al. 1993). A schema for empiric treatment based on severity of disease has been suggested by the ATS (American Thoracic Society 1996) (see Table 6).

Prevention of nosocomial pneumonia depends on prevention of colonization and aspiration and spread of pathogens between patients and staff. Hand washing by staff members should be encouraged. If swallowing is impaired, oral intake should be curtailed and unnecessary nasogastric and endotracheal tubes should be removed. Elevation of the patient's head reduces risk of aspiration (Dal Nogare 1994). Gastric acidity should be maintained by avoidance of H2 antagonists in seriously ill patients.

Aspiration pneumonia

Most aspiration pneumonia is polymicrobial and usually includes anaerobes (Finegold 1994). The latter thrive in lungs injured by chemical pneumonitis. Where there is periodontal disease and gingivitis, anaerobic colonization of the mouth is increased. In hospitalized patients and in nursing homes there is increased oropharyngeal colonization with gram-negative bacilli. A full list of potential organisms that may be involved in aspiration pneumonitis is shown in Table 7.

Pneumonia in patients with a predisposition to aspiration is insidious and mainly affects dependent zones of the lung. The most common site is the posterior segment of the right upper lobe, but the apical segments of the lower lobes can be affected. Lung abscess or empyema with high swinging fever may occur, often with foul-smelling sputum and hemoptysis. Microbiological diagnosis is confounded by the normal anaerobic flora of the mouth and the Gram stain of the sputum is difficult to interpret. Gram stain of empyema fluid or transtracheal aspirate may reveal the characteristic appearance of *Prevotella* spp., *Porphyromonas* spp., and *Fusobacterium* spp. Bacteremia is uncommon in aspiration pneumonia.

Treatment of early uncomplicated aspiration or pneumonia in previously normal individuals is relatively straightforward because the majority of oral anaerobes in this situation are sensitive to benzylpenicillin. In patients with underlying disease or who are hospitalized the frequency of infections with nonpenicillin-sensitive anaerobes is increased, including the *Bacteroides fragilis* group and gram-negative organisms including *Pseudomonas* spp. The possibility of infection with *S. aureus* should also be covered by administration of clindamycin or an aminoglycoside. Alternatively, combination therapy with a broad-spectrum penicillin, such as ticarcillin or piperacillin, plus an aminoglycoside can be given. Newer antibiotics such as imipenem, or a combination of a broad-spectrum antibiotic with a β-lactamase inhibitor, are also effective.

Complications of pneumonia

PLEURAL EFFUSION

Pleural effusions occur very commonly in pneumococcal pneumonia. Usually the effusion is sterile and is absorbed spontaneously within two weeks. Occasionally the effusion is large and requires aspiration. Empyema should be suspected if an effusion persists beyond two weeks, especially if there is continuing fever and pain.

EMPYEMA

Pus in the pleural space leads to symptoms of chest pain, fever, and general malaise. Most empyemas occur as a complication of pneumonia or lung abscess, but 15–30

Table 6 *Summary of clinical setting, organisms, and empiric treatment of nosocomial pneumonia based on severity of disease (adapted in part from the American Thoracic Society 1996)*

Mild or moderate nosocomial pneumonia		
No risk factors	*Core organisms*[a]	*Initial antibiotics*
No unusual risk factors; early onset Early onset	*S. pneumoniae* *H. influenzae* *S. aureus* *E. coli*, *Klebsiella* *Enterobacter* spp. *Serratia* spp.	Second- or third -generation cephalosporin or new fluoroquinolone or β-lactam + β-lactamase inhibitor
With risk factors	*Pathogens*	*Initial antibiotics*
Recent abdominal surgery Witnessed aspiration	Core organisms[a] + anaerobes	Second- or third-generation cephalosporin + clindamycin or new fluoroquinolone alone or β-lactam + β-lactamase inhibitor
High-dose steroids	*L. pneumophila*	Use macrolide or quinolone
Prior hospitalization ICU stay Steroids Prior antibiotics Chronic lung disease	*P. aeruginosa* and MRSA	Treat as severe nosocomial pneumonia
Severe nosocomial pneumonia		
Clinical setting		*Initial antibiotics*
ICU Nursing home Prior antibiotics Respiratory failure Progressive pneumonia Sepsis, shock Organ failure	Core organisms + *P. aeruginosa* + *Legionella pneumophila* + MRSA	Third- or fourth-generation antipseudomonal cephalosporin + quinolone ± vancomycin or third- or fourth-generation antipseudomonal cephalosporin + macrolide ± vancomycin ± aminoglycoside or carbapenem + quinolone ± vancomycin

ICU, intensive care unit; MRSA, methicillin-resistant *S. aureus*.

a) Core organisms are those pathogens commonly implicated in nosocomial pneumonia with no unusual risk factors.

Table 7 *Potential microbial etiology of aspiration pneumonitis*

Anaerobes	Aerobes
Gram-negative bacilli	Gram-positive bacilli
Pigmented *Prevotella* and *Porphyromonas*	*Staphylococcus aureus*
Prevotella aureus, *P. buccae*	*Streptococcus pyogenes*
Prevotella oralis group	'viridans' streptococci
Bacteroides ureolyticus group (especially *B. gracilis*)	Gram-negative bacilli
Bacteroides fragilis group	*Klebsiella pneumoniae*
Fusobacterium nucleatum	*Enterobacter* spp.
Fusobacterium necrophorum, *F. naviforme*, *F. gonidiaformans*	*Serratia* spp.
Gram-positive cocci	*Pseudomonas aeruginosa*
Peptostreptococcus (especially *P. magnus*, *P. asaccharolyticus*,	*Escherichia coli*
P. prevotii, *P. anaerobius*, and *P. micros*	*Proteus* spp.
Microaerophilic streptococci (*Streptococcus intermedius*)	
Gram-positive nonsporing bacilli	
Actinomyces spp.

Bifidobacterium dentium	
Gram-positive spore-forming bacilli	
Clostridium (especially *C. perfringens*, *C. ramosum*)	

Modified after Finegold (1994).

percent occur after thoracic surgery and 10 percent occur in association with intraabdominal infection. Empyema following pneumonia is mostly polymicrobial and anaerobes are present in 75 percent of cases. Empyema after thoracic surgery is more likely to be monomicrobial and due to common nosocomial pathogens such as *S. aureus* and aerobic gram-negative bacilli. Progress of pneumonia to empyema is related to delay in appropriate antimicrobial therapy. Once infection is established the empyema rapidly becomes fibrinopurulent with eventual locule formation in the pleural space and fibrous adhesions between the visceral and parietal pleura. Diagnosis is based on demonstration of purulent pleural fluid. Microbiological diagnosis should include Gram and acid-fast stains, wet mount for fungi, and culture for aerobic and anaerobic bacteria, *Mycobacterium* spp., and fungi. Once an empyema has developed, the aim should be to sterilize the space with antibiotics and establish early and adequate pleural space drainage. Diffusion of antibiotics into the pleural space is good, but aminoglycosides and some β-lactams may be inactivated in the presence of pus, a low pH, and β-lactamase enzymes (Hughes and van Scoy 1991). Empirical treatment of empyema should include an effective agent against anaerobic bacteria and aerobic gram-negative bacteria. Metronidazole may not be reduced to its active metabolite in a partially oxygenated environment and so clindamycin in combination with a fluoroquinolone for 4–6 weeks is a suitable combination. Alternatively, imipenem–cilastatin can be used. Drainage of pus is the mainstay of treatment and in the early exudative phase, closed drainage may suffice. If the empyema is loculated, operation can sometimes be avoided by the judicious use of urokinase to break down adhesions (Robinson and Moulton 1994).

NECROTIZING PNEUMONITIS AND LUNG ABSCESS

Pus-filled cavities in the lung can evolve when there is suppurative lung infection together with destruction of lung parenchyma. Necrotizing pneumonitis is arbitrarily defined as multiple cavities of less than 2 cm in diameter; lung abscesses are larger. Aspiration is the most common predisposing factor and in such cases the microbial etiology reflects that seen in aspiration pneumonitis (see Table 5). Tooth decay and gingivitis also predispose to necrotizing infections. Abscess may also occur in patients with necrotic neoplasms, in patients with bronchiectasis, during septic embolization from another source (e.g. endocarditis), as a complication of pulmonary embolus, and as direct spread from the abdomen (e.g. amoebic abscess).

Pathogenesis

Necrotizing pneumonia after aspiration is common because of the destructive nature of gastric contents and the large microbial load. In the unconscious patient, bacteria can replicate in static fluid in dependent lung segments. Some microorganisms produce necrotizing infections by virtue of their virulence factors, including *F. necrophorum*, *K. pneumoniae*, and *S. aureus*. *P. aeruginosa* secretes toxins that create a local vasculitis in addition to pneumonitis. Bronchiectasis can lead to lung abscess by virtue of markedly impaired local airway clearance.

Microbial etiology

In a study of lung abscess caused by transtracheal aspiration, the majority of patients had multiple isolates but in every case one or more anaerobes was recovered (Bartlett et al. 1974). The most common were gram-negative bacilli, including *Bacteroides* spp. and *Fusobacterium* spp., and also gram-positive cocci, including *Peptostreptococcus* spp. and microaerophilic streptococci. The aerobic organisms that can cause necrotizing pneumonitis are *S. aureus*, *S. pyogenes*, *K. pneumoniae*, *P. aeruginosa*, *Proteus* spp., and *E. coli*. Occasionally the more common causes of community-acquired pneumonia such as *S. pneumoniae* and *L. pneumophila* can be involved in a necrotizing process. *Actinomyces* spp., *Arachnia* spp., and *Nocardia* spp. can cause necrotizing pneumonitis as part of a chronic infection. A number of pathogens cause necrotizing pneumonitis in the context of immunosuppression, including *Burkholderia cepacia*, in patients receiving nebulized therapy (Yamagishi et al. 1993). *Legionella* spp. and *Yersinia enterocolitica* can cause necrotizing pneumonias in such patients. Necrotizing pneumonitis is a prominent feature of *B. pseudomallei* infection (melioidosis) and as part of infection with *B. anthracis* in anthrax and *Y. pestis* in pneumonic plague.

Where multiple abscesses are present in the lung, hematogenous spread from an extrapulmonary focus is the probable cause. *S. aureus* abscesses can complicate right-sided endocarditis, particularly in intravenous drug abusers. Enterobacteriaceae can produce multiple abscesses in association with urinary tract or bowel surgery and anaerobes can do so in patients with pelvic infections.

Diagnosis

Microbiological diagnosis can be achieved by transtracheal aspiration, bronchoscopic alveolar lavage, or with a protected brush specimen. Material should be rendered anaerobic as quickly as possible.

Therapy

For patients who are not severely ill, penicillin plus metronidazole or clindamycin is the initial therapy. Treatment must be continued for up to 3 months to achieve cure. In severely ill patients, empirical antibiotic therapy should aim to reduce the burden of β-lactamase producing anaerobes and also *S. aureus* and gram-negative bacilli, including *P. aeruginosa*. Some anaerobic bacteria, including *Actinomyces* spp. and *Propionibacterium* spp., are resistant to metronidazole. Some strains of the *B. fragilis* group are also resistant to the broad-spectrum penicillins, including piperacillin (Finegold 1994). Severely ill patients with necrotizing pneumonia can be given imipenem or a broad-spectrum β-lactam–β-lactamase inhibitor combination.

Chronic pneumonia

Apart from mycobacteria (see Mycobacterium tuberculosis complex, Mycobacterium leprae and other slow growing mycobacteria and 50, Rapidly growing mycobacteria), *Actinomyces* spp., notably *A. israelii* and *Propionibacterium propionicum*, and *Nocardia asteroides* may cause chronic pneumonia (see Actinomyces and related genera, and 45, Nocardia and other aerobic actinomycetes.

Pneumonia in immunocompromised patients

Most pneumonias in non-HIV immunocompromised patients occur in the context either of neutropenia or T-cell defects. These occur in malignancies, particularly hematological malignancies, with and without chemotherapy; they also occur in patients undergoing organ transplantation and attendant immunosuppressive therapy and in other patients receiving steroids. Neutropenic patients are susceptible to pneumonia due to gram-negative organisms, particularly *E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Serratia* spp., *Proteus* spp., and *Pseudomonas*. They are also susceptible to gram-positive infections, including *S. aureus* and *Staphylococcus epidermidis* and viridans streptococci (Verhoef 1993). Patients with cellular immune defects such as T-cell defects due to cyclosporin, purine antagonists, corticosteroids, or hematological malignancy are vulnerable to pneumonia mainly due to intracellular pathogens such as *Mycobacterium* spp. and *Legionella* spp., but more importantly to viruses, including cytomegalovirus (CMV), commonly derived from the transplanted organ, fungi (*Candida*, *Cryptococcus*) and *P. carinii* (Hughes 1993). It is difficult to distinguish on clinical grounds alone between pneumonia of bacterial or nonbacterial origin, but in general bacterial infections produce a rapidly advancing clinical course with focal infiltrates on chest radiograph (Fanta and Pennington 1994). *P. carinii* pneumonia in the non-HIV setting can also cause a rapidly advancing pneumonia. Bronchoscopy, with bronchoalveolar lavage, is necessary to identify the agents responsible because several may be involved. A number of unusual bacteria cause pneumonia in the immunocompromised host, including *Nocardia* spp., *Bordetella* spp., and *B. cepacia*. Nosocomial outbreaks of pneumonia in immunocompromised patients can be due to *L. pneumophila* (Carratala et al. 1994) and tuberculosis in renal units (Hall et al. 1994). Fanta and Pennington (1994) have proposed a scheme for initiating empirical therapy in immunocompromised

patients. Patients with a focal infiltrate should be given antibacterial treatment while results of lung sampling are awaited. A combination of antibiotics to cover staphylococci and resistant gram-negative bacilli, including *Pseudomonas*, should be given, for example, a third-generation cephalosporin and an aminoglycoside, or a combination of broad-spectrum penicillin and an aminoglycoside. If *Legionella* is suspected, intravenous erythromycin should be added; if *Aspergillus* is suspected, amphotericin B should also be given. The challenging problem of aspergillosis is discussed in the Medical Mycology volume, Aspergillosis.

Bacterial pneumonia in HIV infection

In late-stage unmodified HIV infection, particularly in patients with CD4 counts $<0.2 \times 10^9$ per liter, lung disease is dominated by infection with *P. carinii*, *M. tuberculosis*, *Toxoplasma gondii*, and *Cryptococcus neoformans*. Patients are also susceptible to conventional bacterial infections. HIV-seropositive individuals have increased susceptibility to bacterial pneumonia, particularly caused by *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, *K. pneumoniae*, *N. meningitidis*, *Rhodococcus* spp., and *S. aureus* (Mitchell and Miller 1995). This susceptibility is particularly so in patients with a history of intravenous drug abuse (Caiaffa et al. 1994). Smoking of illicit drugs, such as marijuana and cocaine, is also a risk factor. Patients with AIDS in Africa appear particularly susceptible to pneumococcal disease (Gordon et al. 2002). In patients with relatively normal CD4 lymphocyte counts and no other HIV-related symptoms there is an appropriate response to antibiotic therapy. More advanced immunosuppression increases the risk of bacterial pneumonia (Rosen 1994). In the era of highly active antiretroviral therapy (HAART), there has been a declining morbidity and mortality of patients with AIDS (Palella et al. 1998).

Rhodococcus equi emerged as an important pathogen as a result of the HIV pandemic but is rarely seen in other patients. It is an anaerobic, nonmotile gram-positive organism that causes typical pneumonia which can be necrotizing and associated with pleural effusion. It is sensitive to vancomycin, erythromycin, chloramphenicol, and aminoglycosides. Treatment requires prolonged administration of vancomycin and erythromycin (Guerra et al. 1994). Infection with *H. influenzae* in HIV infection is somewhat unusual in that there is a high frequency of capsulate type b organisms in this group (Casadevall et al. 1992).

HIV-positive individuals have an increased incidence of sinusitis. The organisms involved are similar to those in non-HIV infected individuals, but *P. aeruginosa* is more frequent in the late stages of HIV disease. Occasionally nonbacterial pathogens such as *Cryptococcus*, *Aspergillus*, *Alternaria*, and CMV are responsible. Chronic sinusitis is particularly troublesome in patients with low CD4 counts. Treatment follows general principles.

Patients with HIV infection appear to be more susceptible to chronic bronchitis and bronchiectasis. The most common pathogens responsible for bacterial bronchitis include *H. influenzae* and *S. pneumoniae*, though *Pseudomonas* spp. may also be involved (Verghese et al. 1994). Exacerbations respond promptly to appropriate antibiotic therapy but may recur. Bronchiectasis tends to occur as discrete lesions in single lobes.

PERTUSSIS

Pertussis (whooping cough) is caused by *Bordetella pertussis*. It causes prolonged paroxysms of cough and in the very young can lead to prolonged apnea and death; long-term sequelae include bronchiectasis. There is no effective antibiotic treatment for the paroxysmal stage of the disease and prevention is the lynchpin of management.

Epidemiology

B. pertussis is transmitted by droplets and is highly infectious, with attack rates in susceptible individuals between 50 and 100 percent. Worldwide, there are approximately 50 million cases and 600 000 deaths annually (Crowcroft et al. 2003). Epidemics occur in cycles of 3–5 years, reflecting the appearance of susceptible individuals in a given population. Since 1950 the incidence of pertussis has been modified dramatically by the introduction of the whole-cell vaccine. Vaccination is given to children older than 1 month and provides immunity for approximately 12 years. Before vaccination pertussis was seen mainly in children 1–5 years of age, because of passive protection by maternal antibody in those aged less than 1 year. Adults, including mothers, are generally immune because of natural infection in childhood. In Sweden, where the pertussis programme was terminated in 1979, the incidence of pertussis is 60 cases per 100 000 population; age-specific attack rates per 100 000 have been 630 infants >1 year, 670 in children 1–4 years, and 258 in children 5–9 years (Romanus and Jonsell 1987). In contrast, in Massachusetts, USA, which has an active pertussis programme, the incidence of bacteriologically confirmed pertussis is 0.92 cases per 100 000 population, with a peak incidence in infants aged 1 month (104 per 100 000 population), which then declines to five per 100 000 (Marchant et al. 1994). Vaccination limits disease in children but the peak incidence is now in infants aged 1 month probably because of the absence of passive immunity from mothers in whom vaccine-induced immunity has declined. Even in countries with high coverage, adult pertussis does occur (Gilberg et al. 2002) and there is evidence of

transmission of pertussis from adults to susceptible infants (Mokotoff et al. 1995). During the mid-1970s the general public was alerted by media publicity to the possibility of vaccine-induced brain damage, and this led to a decline in vaccine uptake. Subsequently, there were three large epidemics in the UK at characteristic 4-year intervals in 1977, 1981, and 1985 (Preston 1994). In both Massachusetts (Marchant et al. 1994) and Cincinnati (Christie et al. 1994), there has been a resurgence of pertussis in the past 15 years in the face of vaccination programmes. These are due either to over-reporting or, more worrying, failure of vaccine efficacy.

Pathogenesis

B. pertussis produces a number of virulence factors (see Bordetella). The first step in *B. pertussis* infection is circumvention of mucociliary clearance by binding to ciliated cells and multiplying on their surfaces. This is achieved by two adhesins: filamentous hemagglutinin and pertussis toxin. Filamentous hemagglutinin release facilitates dispersal through the respiratory tract (Coutte et al. 2003). In addition, *B. pertussis* produces serotype 2 and 3 fimbriae, which also facilitate adherence. Colonization of ciliated cells results in their death because of toxin production by the bacterium. This damage to the airway epithelium and direct activity against local neurons by pertussis toxin is responsible for the paroxysmal cough (Salyers and Whitt 1994). *B. pertussis* survives for long periods in phagocytes. Pertussis toxin inhibits phagocyte killing in vitro and the migration of monocytes. The organism can survive in human polymorphs by inhibiting phagosome–lysosome fusion but it does not inhibit the respiratory burst (Steed et al. 1992). Similarly, *B. pertussis* survives for 3–4 days in human monocyte-derived macrophages (Friedman et al. 1992).

Clinical features

After an incubation period of 1–3 weeks a nonspecific catarrhal illness occurs with symptoms of malaise, lethargy, low-grade fever, dry cough, and poor feeding. A week later paroxysms of coughing occur, which increase in pitch before terminating in a deep inspiratory movement accompanied by the typical whoop. Chest examination is usually normal unless pneumonia or lobar collapse has occurred, as it occasionally does in infants. In infants, mortality is due to a combination of apnea and aspiration of vomitus. In adults, the disease tends to be less severe, though typical whooping cough may be seen. Children may be susceptible to bronchial infections for up to a year after pertussis, as the result of reduced host defenses of the airway. Bronchiectasis in some adults has been attributed to severe pertussis in childhood.

Diagnosis

In the presence of the typical whoop, diagnosis presents no difficulty, but isolation of *B. pertussis* by culture is diagnostic. This is most likely during the late catarrhal and early paroxysmal phases, but later becomes progressively less likely. Pernasal pharyngeal swabs should be cultured on Bordet–Gengou agar, supplemented with methicillin or cephalexin to inhibit the normal flora, or patients may be asked to cough directly on to the medium. Cultures must be examined daily for 5–7 days to identify the tiny, slow-growing, hemolytic colonies. In nasopharyngeal smears, *B. pertussis* can be detected directly with fluorescent antibody. Serological tests are not used routinely for the diagnosis of pertussis, but agglutinins and complement-fixing antibodies can be detected in serum and antipertussis secretory IgA can be detected in nasopharyngeal smears. PCR-based detection is also available but is not more sensitive than culture (Lingappa et al. 2002). Laboratory confirmation of pertussis can be difficult, but a cough lasting 2 weeks during community outbreaks is a sensitive and specific marker. Other organisms, including coxsackie viruses, echoviruses, adenoviruses serotypes 1–3, 5, and 7, and *M. pneumoniae*, can cause illness clinically indistinguishable from pertussis.

Management

Treatment during the early stage of the disease can reduce its course and restrict transmission. Erythromycin is recommended for cases and their household contacts, regardless of age or vaccination status. It is important to protect children aged less than 6 months who are too young to vaccinate. Chemoprophylaxis should be given to contacts as early as possible because more than 21 days after first contact it is of limited value (Mokotoff et al. 1995).

Prevention

Whole-cell vaccine can be combined with diphtheria and tetanus toxoids and aluminum-containing adjuvants (DTP vaccine), but an acellular vaccine has been introduced in several parts of the world. The pertussis component of this contains the three major agglutinogens, 1, 2, and 3. It is administered as three primary doses at intervals of 2 months beginning at 6–8 weeks of age. Booster doses are given 6–12 months later, and the third dose is given at 4–6 years of age. The vaccine is believed to have an effectiveness greater than 80 percent in preventing pertussis, but there has been a decline in efficacy in recent years (reviewed by Preston 1994). The

duration of protection is limited and wanes by approximately 12 years after immunization. Vaccine failures have been attributed to omission of one of the three agglutinogens or omission of the adjuvant.

A major problem with whole-cell vaccine has been public reaction to reports of adverse effects. Pertussis incidence has been 10–100 times lower in countries that have maintained higher coverage (Gangarosa et al. 1998). The most common of these are local reactions at the injection site and high fever; convulsions and brain damage are rare. The risk of permanent neurological damage in normal children given a full course of DTP vaccination is approximately one in 100 000, which is less than that of complications from the disease. Vaccination should, however, be avoided in children with a history of convulsions or brain damage in the neonatal period or other neurological disorder and during a febrile illness. A history of idiopathic epilepsy or developmental delay due to neurological disease in first-degree relatives is a relative contraindication that should be individually assessed. Those who have had a serious local or systemic reaction to a dose of vaccine should not be given further doses.

These considerations led to an effort to develop acellular vaccines. Pertussis toxin (PT), filamentous hemagglutinin (FHA), 68-kDa outer-membrane protein (OMP), and fimbrial agglutinogens are the most important antigens that elicit protective immunity against pertussis. FHA and OMP are, together with chemically detoxified PT, the components of some new acellular pertussis vaccines. During a pertussis outbreak in previously immunized children, those with higher serum levels of anti-FHA antibodies remained healthy, whereas those with lower antibody levels developed the disease (He et al. 1994). Formulations of acellular vaccine containing FHA, PT, and agglutinogens have been effective since 1981 in Japan in children 24 months of age and older. Pertussis toxoid alone or in combination with FHA has been tested in Swedish children from 6 months of age and gave partial protection against infection and good protection against severe disease (Ad hoc Group for the Study of Vaccines 1988). Five- and three-component acellular vaccines have been shown to be as effective as the whole-cell vaccine against culture-confirmed pertussis with at least 21 days of paroxysmal cough, though the five-component vaccine was superior to the three-component vaccine in preventing mild disease (Olin et al. 1997). Acellular vaccines can be effectively used as boosters. They are expensive and do not give rise to type-specific agglutinins. However, multicomponent acellular pertussis vaccines do appear to be effective and show fewer adverse effects than whole-cell pertussis vaccines. In areas where whooping cough is more likely to be fatal, it is possible that the higher toxicity of some whole-cell vaccines may be offset by their increased effectiveness (Tinnion and Hanlon 2000).

Infections with *Bordetella* species other than *B. pertussis*

Bordetella parapertussis has been incriminated as a minor cause of whooping cough, particularly a milder form than that caused by *B. pertussis*. Some evidence suggests that *B. parapertussis* may not be a separate species; this includes the isolation of both *B. pertussis* and *B. parapertussis* from whooping cough patients and the apparent conversion of *B. pertussis* to *B. parapertussis* by loss of a prophage. Doubt has been cast on *Bordetella bronchiseptica* as a possible cause of whooping cough (Woolfrey and Moody 1991).

ACUTE BRONCHITIS

Acute bronchitis is manifest as productive cough in a patient without a history of chronic chest disease. The microbial etiology of acute bronchitis includes viruses, particularly adenovirus, influenza virus, respiratory syncytial virus, and parainfluenza virus, the latter two being particularly common in children. *M. pneumoniae* and the pneumococcus are the prominent bacterial causes of acute bronchitis (Pennington 1994a). On balance, antibiotic therapy is regarded as unnecessary (reviewed by Gonzales and Sande, 1995). Randomized double-blind studies have failed to show a major clinical role for antibiotics in uncomplicated acute bronchitis. Some patients with acute bronchitis experience a prolonged episode of bronchial hyperreactivity. Antibiotics do not alter this syndrome.

CHRONIC BRONCHITIS AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic bronchitis is defined as the daily production of sputum for at least three consecutive months in two consecutive years and its essential feature is chronic bronchial mucin hypersecretion. This may be accompanied by bacterial infection, which causes an increase in the purulence of sputum, and also generalized small-airway obstruction. As a result, patients may experience one of three entities of increasing severity. These are simple chronic bronchitis with cough productive of non-purulent phlegm, chronic or recurrent mucopurulent bronchitis with cough, and chronic obstructive bronchitis, in which sputum is mostly purulent and there is airways obstruction (Medical Research Council 1965). Each of these is subject to acute exacerbation with a decline in the clinical state of the patient. The term chronic obstructive pulmonary disease (COPD) describes a range of chronic entities associated with airflow obstruction, including chronic bronchitis, emphysema, chronic asthma, and bronchiectasis. The disease COPD is characterized by episodic exacerbations in which there is fever plus any combination of increased

dyspnea, increased sputum purulence, or increased sputum volume. It is unclear whether exacerbations are associated with accelerated loss of lung function during the natural history of chronic bronchitis (Bates 1973), but following an exacerbation most patients experience at least a temporary decrease in functional status and quality of life (Seemungal et al. 1998).

Pathogenesis

Smoking plays a part in the generation of chronic bronchitis (Floreani et al. 1994). Gradually there is increased mucus hypersecretion, depressed ciliary function, and epithelial cell injury. Bacteria that are not normally present in the airway below the larynx are then able to colonize the diseased epithelium (Read et al. 1991) (Figure 5) and this leads to further damage.

Bacterial infection and exacerbations of chronic bronchitis

Nontypable *H. influenzae* is most commonly present in acute, purulent exacerbations of chronic bronchitis, but *S. pneumoniae* and *M. catarrhalis* can also be isolated. *H. influenzae* adheres to mucus via fimbriae (Barsum et al. 1995) and galactoside sequences on epithelial cells (Krivan et al. 1988). Soluble products of *H. influenzae* reduce ciliary beat frequency (Wilson et al. 1985) and mucociliary clearance. Nontypable *H. influenzae* are present in the lower respiratory tract of most patients with chronic bronchitis and in all patients at some time, even between exacerbations. Molecular typing of strains of *H. influenzae* isolated from sputum of patients with COPD has demonstrated that a single strain may persist for many months within the lower respiratory tract mucosa and remains present even if there have been acute exacerbations of COPD that have been treated with antibiotics (Groenveld et al. 1990). Multiple strains of *H. influenzae* can be present simultaneously in the sputum of an individual with COPD, and these distinct isolates may even vary in their antimicrobial sensitivity (Murphy et al. 1999). Their presence in the sputum during periods of increased symptoms does not necessarily imply a pathogenic role, but such a role for *H. influenzae* has been suggested by Musher et al. (1983), who showed that the serum of patients with acute febrile bronchitis contains opsonizing antibody for their own sputum isolates. There is evidence that acquisition of strain variants of *H. influenzae*, *M. catarrhalis*, or *S. pneumoniae* is associated with exacerbated disease, based upon molecular typing of sputum isolates from patients with COPD (Sethi et al. 2002). Virus and mycoplasma infections are responsible for up to a third of the acute exacerbations of chronic obstructive airways disease; the viruses more commonly isolated include influenza A, parainfluenza virus, coronavirus, rhinovirus, and herpes simplex virus (reviewed by Floreani et al. 1994). This suggests that bacteria, such as *H. influenzae*, flourish in the airways when viral infection further damages already compromised host defenses. The role of *H. influenzae* and *S. pneumoniae* in bacterial infection during chronic obstructive pulmonary disease has been reviewed by Murphy and Sethi (1992).

M. catarrhalis is present in pure culture in some transtracheal aspirates and is a recognized pathogen in chronic bronchitis; improvement is seen with specific treatment for *M. catarrhalis* infection. The organism has also been isolated from the blood and pleural fluid of patients with chronic obstructive airways disease (Murphy and Sethi 1992). In patients with more severe chronic bronchitis, a wider range of bacteria, including gram-negative enteric bacilli, *Pseudomonas* spp., and *Stenotrophomonas* spp., can be isolated by protective specimen brush (Soler et al. 1998).

Culture of sputum is of doubtful value because it is likely to be contaminated with the potential pathogens that are also present in oropharyngeal secretions. If such examination is undertaken, care should be taken to ensure that only purulent sputum is examined. This should be homogenized and serial dilutions examined. Examination of mucoid sputum will not yield useful information.

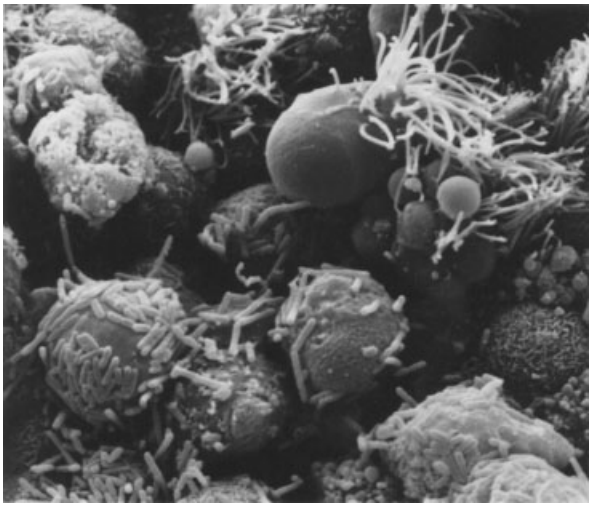

Figure 5 *Scanning electron micrograph of nontypable* Haemophilus influenzae *adhering to damaged areas of airway mucosa. (A. Brain and R.C. Read.)*

Therapy of exacerbations of chronic bronchitis

The use of antibiotics in all but the most severely ill patients is controversial (Saint et al. 1995). Small studies have either shown a positive effect of antibiotics (Berry et al. 1960; Pines et al. 1968), or no effect (Elmes et al. 1965; Nicotra et al. 1982). In a large placebo-controlled study,

Anthonisen et al. (1987) found significant benefit from antibiotics in severe but not in mild exacerbations. Airway function also recovered more rapidly with antibiotic treatment. The use of prophylactic antibiotics is controversial; their use can reduce the frequency and length of exacerbations to a very small degree but is complicated by side-effects of the antibiotics (Black et al. 2002).

It is appropriate to treat severe exacerbations of COPD with antibiotics capable of covering *H. influenzae* and *S. pneumoniae* (Bach et al. 2001). Rates of resistance to aminopenicillins and macrolides of sputum isolates of *H. influenzae* and *S. pneumoniae* are rising throughout the world (Felmingham and Gruneberg 2000). Although antibiotic therapy in patients with mild disease is controversial, appropriate antibiotics include amoxycillin (provided local β-lactamase activity is at low level), co-amoxiclav, or the oral cephalosporins and the macrolides, but erythromycin has relatively poor activity against *H. influenzae*. Newer macrolides such as clarithromycin and azithromycin are better orally tolerated and have greater activity against *H. influenzae* in vitro. New fluoroquinolones are highly active against *H. influenzae* and *S. pneumoniae* and penetrate tissue and sputum well.

BRONCHIECTASIS

Bronchiectasis is permanent abnormal dilation of bronchi accompanied by suppurative inflammation that results in intermittent production of large quantities of purulent sputum. The most common causes are severe parenchymal infections of the lung, including pertussis and measles in childhood and also – most importantly in the developing world – tuberculosis. Foreign bodies, carcinoma, AIDS, allergic bronchopulmonary aspergillosis, and certain congenital abnormalities, including immunoglobulin deficiencies and ciliary abnormalities, can also give rise to bronchiectasis. Cystic fibrosis is associated with bronchiectasis (see Cystic fibrosis). It may also be seen in patients with the α_1-antiprotease deficiencies and is associated with rheumatoid arthritis and inflammatory bowel disease. Once bronchiectasis is present, repeated infections serve to maintain a vicious circle of inflammation and damage to the already compromised airway, which leads to further infection (Cole and Wilson 1989).

The sputum flora of such patients often yields a mixed growth, but *H. influenzae* is probably the most important in sustaining continued infection and inflammation. *S. aureus* and *S. pneumoniae* are also prominent. In established disease, *P. aeruginosa* is associated with a poor prognosis (Angrill et al. 2002). Diagnosis of bronchiectasis is made on the basis of chronic daily production of mucopurulent sputum and confirmed by high-resolution computed tomography (CT), of the thorax (Barker 2002) (Figure 6).

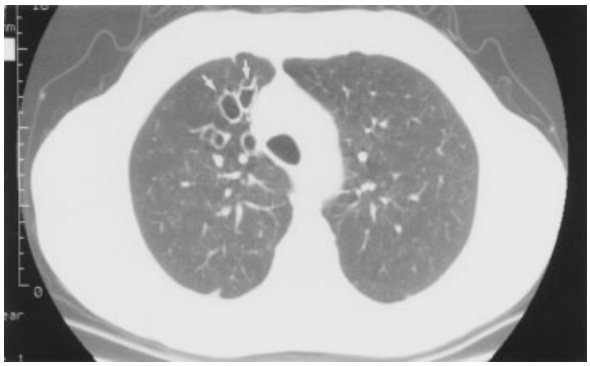

Figure 6 *Computed tomography (CT) scan demonstrating dilated airways and bronchial wall thickening in a patient with bronchiectasis. (Courtesy of A. Nakielny.)*

Management

The mainstay of treatment of bronchiectasis is drainage, which reduces the frequency of exacerbations, and antibiotic therapy. β-Lactam antibiotics do not penetrate diseased tissue at conventional dosages, but high doses of amoxycillin are effective in terminating exacerbations (Cole and Wilson 1989). High doses of oral cephalosporins or quinolones are effective when β-lactamase-producing strains are isolated. Long-term oral antibiotics are well tolerated and lead to symptomatic improvement but ciprofloxacin-resistant *P. aeruginosa* may be troublesome (Rayner et al. 1995). The use of prophylactic aminoglycosides given by nebulizer can reduce bacterial load but does not alter pulmonary function (Barker et al. 2000). In very severe exacerbations the use of intravenous antibiotics effective against *H. influenzae* and *P. aeruginosa* is indicated. Mucolytics have been suggested as adjunctive therapy for bronchiectasis but there is not currently enough evidence to evaluate this. High doses of bromhexine coupled with antibiotics may help with sputum production and clearance (Crockett et al. 2000).

CYSTIC FIBROSIS

Cystic fibrosis (CF) is the most common lethal genetic disease in Caucasians. It is autosomal recessive and caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene located on chromosome 7. Classic CF is characterized by chronic bacterial infection of the airways and sinuses, fat malabsorbtion due to pancreatic exocrine insufficiency, infertility in males due to obstructive azoospermia, and elevated concentrations of chloride in sweat. Patients with partial expression of *CFTR* usually have no overt signs of pancreatic insufficiency and later onset of bacterial infections of the airways (Knowles and Durie 2002). The incidence is approximately one in every 3 300 live Caucasian births. In the airways thick tenacious sputum

causes obstruction, leading to recurrent infection. Patients with CF have airway inflammation that commences at birth (Cantin 1995). The carrier rate is about 5 percent in Caucasians; about 6 000 people have the disease in the UK.

Clinical features

Infants present with meconium ileus at birth or a little later with diarrhea or malabsorption, failure to thrive, or progressive cough. Patients may also present with recurrent pneumonia. Acute exacerbations occur with increased sputum production, cyanosis, dyspnea, fever, and weight loss. Patients also suffer with nasal polyposis and chronic sinusitis.

Role of microbial infection

The first pathogen to colonize children with CF is *S. aureus*. This produces α- and δ-toxins that induce bronchial wall injury and abscess formation. The intense inflammatory response to *S. aureus* leads to further tissue destruction.

Staphylococcal airway injury permits colonization by *P. aeruginosa*. This is the major pathogen implicated in lung function decline and ultimate mortality in CF patients (Lyczak et al. 2002). Patients are at first colonized with nonmucoid strains, but later mucoid variants emerge. The extracellular alginate that they produce increases their adherence to ciliated epithelium (Marcus and Baker 1985). Despite the high antibody levels present against such strains and intensive antibiotic therapy, they cannot be eradicated completely. They reappear after treatment but it is not clear whether this is due to recolonization or acquisition of a new strain (Ojeniyi 1994). Alginate also interferes with antibody coating and inhibits phagocytosis of *P. aeruginosa* (Baltimore and Mitchell, 1980). Bacterial proteases produced by *P. aeruginosa* cause significant damage to the airways. Pseudomonas elastase and alkaline protease are secreted in vivo over prolonged periods in the airways (Suter 1994). *Pseudomonas* elastase increases the permeability of epithelial cells, destroys tight junctions, and induces shedding of epithelial cell-surface heparan sulfate proteoglycans, each of which encourages persistent colonization (Park et al. 2001).

The *Pseudomonas* phenazine pigments pyocyanin and 1-hydroxyphenazine interfere with mucociliary function (Wilson et al. 1987); the membrane glycolipid, the hemolysin rhamnolipid, also reduces mucociliary transport in vivo (Read et al. 1992). Exotoxin A produced by most colonizing strains of *P. aeruginosa* causes tissue injury and is highly immunogenic. Patients become colonized for years with *P. aeruginosa*, often with the same strain, and isolates from sputum relentlessly exhibit multiple antibiotic resistance. It has been demonstrated that the lungs of patients with CF provide an environment ideal for hypermutable strains of *P. aeruginosa* (Oliver et al. 2000).

Noncapsulate *H. influenzae* is most frequently isolated from infants more than a year old. *Burkholderia cepacia* also colonizes CF patients and is transmissible between close contacts. It is occasionally responsible for a fulminating septicemia. This organism produces a number of potential virulence factors, including adhesins, extracellular polysaccharide, lipopolysaccharide, and extracellular enzymes, including proteases and lipases. Some *B. cepacia* genomovars worsen prognosis of patients, whereas others do not (Jones et al. 2001). It is intrinsically highly resistant to antibiotics, including those effective against *P. aeruginosa* (Wilkinson and Pitt 1995), but it is usually sensitive to trimethoprim–sulfamethoxazole and chloramphenicol. *Stenotrophomonas* (*Xanthomonas*) *maltophilia* also colonizes patients with CF and can result in disease, though it does not adversely affect overall prognosis. A range of other microorganisms, including the Enterobacteriaceae, *Candida albicans*, *Aspergillus* spp., and environmental mycobacteria, may also be isolated from these patients, but their significance is uncertain.

Although CF patients produce markedly elevated titers of local and systemic antipseudomonal antibodies, the elastase produced by *P. aeruginosa* interferes with their activity by cleaving off the Fab and Fc fragments of immunoglobulins so that they are unable to interact with receptor sites on pulmonary macrophages or neutrophils (Thick et al. 1985).

Antimicrobial therapy

Antimicrobial therapy of exacerbations should always be guided by sensitivity data from cultured specimens. There is continuing controversy over the use of antibiotics as prophylaxis in CF. Once disease is established, some physicians attempt to suppress sputum colonization with long-term administration of antibiotics. Such antibiotics include cephalexin, oral chloramphenicol, trimethoprim–sulfamethoxazole, and co-amoxiclav, but controlled evaluations of this approach are lacking because of obvious methodological problems with such studies (Chartrand and Marks 1994). The use of oral cephalexin as prophylaxis suppresses *S. aureus* colonization but is associated with increased likelihood of *P. aeruginosa* colonization (Stutman et al. 2002). Most centers treat only acute exacerbations of pulmonary infection, with inclusion of empirical antipseudomonas and *S. aureus* antibiotics. This requires combined antibiotic therapy with a β-lactam plus an aminoglycoside. With the genesis of monotherapy capable of activity against both these pathogens, outpatient administration has flourished. Such antibiotics include ceftazidime, the penems, monobactams, and some β-lactam–β-lactamase

inhibitors. Unfortunately monotherapy can result in the spread of resistant organisms, e.g. *P. aeruginosa*, and this has been demonstrated following the use of ceftazidime (Pedersen et al. 1986). Emergence of *P. aeruginosa* resistance is also seen after monotherapy with imipenem and aztreonam (Chartrand and Marks 1994). The use of oral quinolones has permitted more flexible management of exacerbations. They have been used in children with CF (Schaad et al. 1991) without side effects and their use in moderately severe CF exacerbations can be as effective as traditional intravenous treatment with β-lactams plus aminoglycosides. In vitro susceptibility of isolates returns when the quinolones are withheld for 3 months. The use of aerosolized antibiotics has been advocated but controlled data to support this are limited. Aerosolized *tobramycin* given by nebulizer has been shown to eradicate *P. aeruginosa* (Ramsey et al. 1999) and improve pulmonary function tests (Smith et al. 1989), but emergence of resistance is a problem.

Other forms of therapy

Inhaled corticosteroids are being increasingly used in adults and children with CF to reduce lung damage arising from inflammation, but there is no clear evidence for their efficacy (Dezateux et al. 2000). There is potential to ameliorate the pulmonary disease in CF with somatic gene therapy. The optimal mode of delivery of the normal gene into airway epithelium is under investigation. Adenovirus vectors, DNA–liposome complexes, adeno-associated viral vectors, and DNA–ligand complexes have been used effectively in vitro and have been tested in animals. Adenovirus vectors and DNA–liposome complexes are currently in phase 1 clinical trial. There has been transient correction of electrophysiological defects in human CF nasal epithelium (O'Neal and Beaudet 1994). At present, CF patients face the prospect of lung transplantation as their only salvation once extreme disease ensues. Single-lung, double-lung, and heart–lung transplantation have all been used with success in such patients, and because the transplanted lung retains the physiological characteristics of the donor, there is no tendency for colonization by *P. aeruginosa* over and above that seen in transplanted lungs in non-CF patients.

Bacterial infections of the genital tract

CATHERINE ISON

Genital tract infections	1	Bacterial vaginosis	9
Neisseria gonorrhoeae	2	*Streptococcus agalactiae*	12
Treponema pallidum	6	*Staphylococcus aureus*	12
Haemophilus ducreyi	7	Other bacterial causes of genital tract infections	13
Klebsiella (Calymmatobacterium) granulomatis	9	References	13

The lower genital tract in women has its own microbial flora and in men is often colonized, although this may be a transient flora following sexual intercourse. In contrast, the upper genital tract in men and women is believed to be sterile. It was Doderlein in 1894 who first described lactobacilli as part of the 'normal flora' of the vagina. He believed that the lactic acid produced by lactobacilli from glucose in the vaginal fluid kept the vagina at an acidic pH, which discouraged colonization by other organisms. Glucose is produced from glycogen by the vaginal epithelium and this is utilized by the lactobacilli producing lactic acid. Glycogen is found on vaginal epithelium after puberty and is under estrogen control, hence is seldom present in premenarchal girls or postmenopausal women, unless on hormone replacement therapy. Lactobacilli are therefore found mostly in the vaginal fluid of women of child-bearing years and are considered 'normal' flora. In latter years it has been evident that the production of hydrogen peroxide (H_2O_2) by some lactobacilli is toxic to other bacteria and that this, in addition to lactic acid, may exert a protective effect in the vagina (Hillier 1998). The prevalence of H_2O_2-producing lactobacilli has been shown to be between 42–74 percent in pregnant women (Hillier et al. 1992, 1993; Puapermpoonsiri et al. 1996) and 65 percent in nonpregnant women (Hawes et al. 1996). In premenarchal girls the prevalence is low, 11 percent (Hill et al. 1995), although postmenopausal women have intermediate levels, 38 percent (Hillier and Lau 1997). Hydrogen peroxide has been shown to be toxic to bacteria associated with bacterial vaginosis, *Gardnerella vaginalis* and *Bacteroides bivius* (Klebanoff et al. 1991) and to the human immunodeficiency virus (Klebanoff and Coombs 1991) supporting the hypothesis that lactobacilli play a major role in protecting the vagina from specific pathogens.

Lactobacillus acidophilus and *Lactobacillus fermentum* have been demonstrated in early studies to be the predominant species in the vagina (Ragosa and Sharpe 1960; Giorgi et al. 1987). However, this may be inaccurate as the use of molecular methods identified *Lactobacillus crispatus* and *Lactobacillus jensenii* as the predominant species (Johnson et al. 1980). It appears that the capacity for the organism to produce H_2O_2 is more important than the individual speciation, being more persistent in the vagina than H_2O_2-negative strains.

GENITAL TRACT INFECTIONS

Disruption of the normal ecology of the genital tract can result by acquisition of a sexually transmitted pathogen such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Treponema pallidum* (Table 1) or by increased numbers of bacteria that comprise part of the normal flora, generally in small numbers, such as *G. vaginalis* and group B streptococci (Table 1). Infections due to chlamydia are dealt with in Chlamydia. In many instances the change in ecology will result in symptoms, encouraging the individual to seek care, but

Table 1 *Clinical presentation of bacterial infections of the genital tract*

Organism	Main clinical presentation
Primary pathogens	
Neisseria gonorrhoeae	Uncomplicated infection (*cervicitis*, urethritis, pharyngeal, rectal) Complicated infection (salpingitis, PID, prostatitis, epididymitis)
Treponema pallidum	Genital ulceration Systemic infection
Haemophilus ducreyi	Genital ulceration
Klebsiella granulomatis	Genital ulceration
Secondary pathogens	
Gardnerella vaginalis	Bacterial vaginosis
Prevotella spp.	
Peptostreptococci	
Mobliuncus spp.	
Streptococcus agalactiae	Aerobic vaginitis Asymptomatic carriage
Staphylococcus aureus	Toxic shock syndrome
Clostridium perfringens	Post-partum infection Septic abortion
Actinomyces spp.	Discharge associated with IUCD

in some instances the bacteria remain silent causing asymptomatic infection which may remain undetected. The majority of infections present as mucosal infections of the lower genital tract where the challenge is to diagnose the infecting agent from amongst the resident microflora. However, many of these bacteria can ascend to the upper genital tract, which is normally sterile, to cause more complicated infections such as pelvic inflammatory disease with the possible sequelae of infertility, or, on occasions, can invade the blood causing systemic infections such as toxic shock syndrome. This chapter will first consider those bacteria that are primary pathogens, where their isolation always indicates the need for antimicrobial therapy, and then the bacteria that are secondary or opportunistic pathogens, where isolation needs interpretation together with clinical information before therapy is initiated.

NEISSERIA GONORRHOEAE

Neisseria gonorrhoeae and *Chlamydia trachomatis* (see Neisseria and Chapter 78, Chlamydia) are
the major causes of bacterial sexually transmitted infection in the industrialized world. *N. gonorrhoeae* is primarily a mucosal pathogen that causes infection of the lower genital tract in men and women, occasionally ascends to the upper genital tract to cause complicated infection, and rarely invades the blood to cause disseminated disease. Uncomplicated gonococcal infection (UGI) is predominantly a mucosal infection of the lower genital tract. In men, the primary site of infection is the urethra causing a discharge and/or dysuria and is symptomatic in most of the patients. Rectal infections are common among men who have sex with men and pharyngeal infection can occur in men or women who have oral sexual intercourse and is generally asymptomatic. In women, the primary site of colonization is the cervix, where the organism attaches preferentially to the columnar epithelium rather than the squamous epithelium of the vagina. In contrast to gonorrhea in men, infection in women is often asymptomatic in at least 50 percent of patients. Colonization of the urethra and rectum in women does occur but it is often unclear whether this is a true colonization or is leakage of cervical secretions from the vagina.

N. gonorrhoeae presents as a lower genital tract infection in >90 percent of patients in most parts of the world but can ascend to cause complicated gonococcal infection (CGI) of the upper genital tract. It presents as salpingitis or pelvic inflammatory disease in women and epididymitis or prostatitis in men. Complicated infection occurs more commonly in women than in men, largely because of undiagnosed asymptomatic infection. Disseminated gonococcal infection, where the organism invades into the blood to cause systemic infection, is a separate entity and is rare. It presents primarily as a rash, septicemia, and arthritis and is associated with certain strains of gonococci and is more prevalent in individuals with deficiency in the terminal complement components.

N. gonorrhoeae is an obligate human pathogen with no other natural host, which can cause repeated infection in the same host with no apparent immunity. This is believed to result from its ability for phase and antigenic variation, allowing the organism to appear novel at each infection. *N. gonorrhoeae* is genetically diverse and highly competent for genetic exchange and recombination at all stages of its life cycle, resulting in a nonclonal or panmictic population. In vivo, this probably occurs during mixed infections which are more likely to occur in sexually active individuals with high rates of partner change.

N. gonorrhoeae possess pili, small appendages, which enable the organism to overcome the hydrophobic interactions between the organism and the epithelial cell and hence come into close proximity, allowing specific receptors to attach to the host cell surface. Attachment is then enhanced by a family of outer membrane proteins, Opa proteins. *N. gonorrhoeae* are then believed to adhere to the epithelial cell, mediated by Opa proteins which interact with two receptors on the epithelial cells, CD66 and the heparan sulfate proteoglycans. The bacteria–epithelial cell interaction also induces a proinflammatory cytokine response. Invasion then occurs and the major porin, Por, is believed to play an important

role in this and also induces apototic cell death of both epithelial cells and polymorphs (Naumann et al. 1999).

Diagnosis

PRESUMPTIVE DIAGNOSIS

Microscopy is used for the presumptive diagnosis of gonorrhea in most parts of the world and is simple to perform and gives a result quickly. The presence of intracellular gram-negative diplococci in smears is considered diagnostic and in urethral smears from symptomatic men has a sensitivity of >95 percent. However, in women or asymptomatic men, the sensitivity is between 30–50 percent (Ison 1990; Sherrard and Barlow 1996; Jephcott 1997). This difference is probably due to higher numbers of bacteria being present in symptomatic individuals, which are easily detected by microscopy, compared to considerably lower numbers present in asymptomatic individuals which are below the detection limit. The sensitivity is also lower for rectal smears due to the large numbers of other bacteria present, including other gram-negative cocci, and is really only reliable when specimens have been taken from a lesion through a proctoscope, rather than perianal or blind rectal swabs. Microscopy is not commonly used for examining pharyngeal specimens. The specificity of the Gram stained smear for the presumptive diagnosis of gonorrhea is usually high when performed by experienced personnel (Hook and Handsfield 1999; Knapp and Koumans 1999). Comparison of numbers of positives obtained by Gram stained smears and culture can give an indication of either problems with reading smears or of isolation techniques, the correlation between smear and culture for urethral specimens from symptomatic men should be more than 95 percent.

CONFIRMATORY DIAGNOSIS

Isolation of the causative organism, *N. gonorrhoeae*, is still considered necessary for the confirmation of the diagnosis of gonorrhea, whenever the resources are available. The sensitivity of culture is thought to be high, 80–100 percent, but is dependent on a good specimen and isolation procedure. A nutritious agar base is required for the growth of *N. gonorrhoeae*, which is a fastidious organism, supplements containing an iron source and selective agents. The mostly commonly used agar base is GC agar base, which contains a mixture of peptones, starch, and agar, alternatively Columbia agar can be used. Blood, either lysed, heated (chocolatized) or pure hemoglobin, is often used as a supplement providing both amino acids and iron. Nonblood based supplements include IsoVitaleX or Vitox, which are an equivalent alternative. The use of selective agents to suppress the normal flora is recommended, particularly for specimens taken from the lower genital tract in women or from the rectum. Vancomycin or lincomycin is added to suppress gram-positive cocci, colistin and/or trimethoprim to inhibit other gram-negative organisms, and nystatin or amphotericin to suppress yeasts. Strains susceptible to the vancomycin, *env* mutants, and trimethoprim have been reported and can cause false negative results. In an ideal situation, both nonselective and selective isolation media would be used but there are seldom resources available for both and if a single medium is to be used it should contain selective agents to prevent overgrowth of the *N. gonorrhoeae* by the resident normal flora. Incubation at 36–37°C in a high humidity (>90 percent) and increased carbon dioxide concentration (5–10 percent) should be for a minimum of 48 h before the isolation medium should be discarded as negative.

Preliminary identification of any resulting colonies as oxidase positive gram-negative cocci is a presumptive identification of *Neisseria* spp. In many countries where resources are limited, no further identification is performed but it is still standard practice, where possible, to confirm the identity as *N. gonorrhoeae*. Historically, *N. gonorrhoeae* was identified by its ability to produce acid from glucose but not from other carbohydrates such as maltose, sucrose, and lactose. Carbohydrate utilization has now been combined with other preformed enzymes, such as the aminopeptidases, in identification kits, which give a result within 4 h. These tests will fully speciate the organism under test and are particularly useful for laboratories that encounter only occasional isolates. Biochemical reactions of the clinically important *Neisseria* spp. are shown in Table 2.

Table 2 *Identification of* Neisseria gonorrhoeae *from the clinically important* Neisseria *spp. and* Branhamella catarrhalis

	Acid production from				Aminopeptidase			
Organism	Glucose	Maltose	Sucrose	Lactose	γ-glutamyl	Propyl	DNAase	Butyrate esterase
N. gonorrhoeae	+	–	–	–	–	+	–	–
N. meningitidis	+	+	–	–	+	V	–	–
N. lactamica	+	+	–	+	–	–	–	–
N. cinerea	–	–	–	–	NK	NK	–	–
B. catarrhalis	–	–	–	–	–	–	+	+

NK, not known; V, variable result.

Alternatively, there are immunological reagents available that can identify *N. gonorrhoeae* and eliminate *N. meningitidis* and *N. lactamica* but do not give a full speciation. There are two reagents commonly used which both contain monoclonal antibodies to the major porin, Por. The antibodies are either linked to staphylococcal protein A and used in a coagglutination test (Phadebact Monoclonal GC Test, distributed by Boule in the UK) or linked to fluorescein and used in an immunofluoresence test (Syva Microtrak *Neisseria gonorrhoeae* Culture Confirmation Test, distributed by Launch Diagnostics in the UK). Both these reagents contain mixtures of antibodies to specific epitopes rather than a single antibody to a conserved epitope, hence strains giving false negative results do occasionally occur. Fortunately, the mixtures in each of these reagents differ and so they complement each other, rarely both giving a negative result. The coagglutination test has the advantage that it will also divide gonococcal isolates into two groups, PIA (WI) or PIB (WII/III), allowing a preliminary typing of strains.

MOLECULAR DETECTION

Detection of *N. gonorrhoeae* directly in the specimen can be achieved using probes or by amplification of specific sequences of DNA. The advantage of these tests are that they are highly sensitive and can detect small amounts of DNA and that they can detect nonviable organisms. Unlike previous attempts at antigen detection using immunological approaches, molecular detection methods are also highly specific. This is particularly important for screening low prevalence populations. The disadvantage of using molecular detection for *N. gonorrhoeae* is that susceptibility testing still requires a viable organism.

Molecular detection for gonorrhea has not been as widely used as for chlaymdial infection, largely because existing diagnostic testing has performed satisfactorily and has been less expensive. However, nucleic acid amplification tests (NAAT) has been shown to have a higher sensitivity than culture in some studies, particularly in situations where the resources or facilities for culture are not ideal. They have the added advantage that they can be used with noninvasive samples such as urine or self-taken swabs or tampons. The widespread use of NAATs for chlamydial infection has encouraged the use for gonorrhea as most of the commercial kits can test for both organisms on the same sample.

The nucleic acid hybridization test (Gene Pace 2) has a high sensitivity and specificity when used with endocervical or urethral specimens (Koumans et al. 1998). However because of the lack of amplification, they are likely to be less sensitive than the NAATs. The sensitivity of NAATs using amplification by polymerase chain reaction (Amplicor, Roche) or strand displacement amplification (BD Probtec, Becton Dickinsen) on endocervical specimens (van Dyck et al. 2001) or self-taken swabs or tampons (Knox et al. 2002) is high and often higher than culture. However, they are less satisfactory for detection of *N. gonorrhoeae* in urine from women (Van Doornum et al. 2001). Sensitivity is high when either urethral swabs or urine are used in men (Van Doornum et al. 2001; Palladino et al. 1999; Akduman et al. 2002). The specificty is high with all these tests but confirmation of positive results should be considered, particularly when low prevalence populations are screened.

SUSCEPTIBILITY TESTING

The purpose of susceptibility testing is to predict the outcome of therapy. In many instances for gonorrhea the patient will have been treated before the result of the susceptibility testing is known. The choice of a first line therapy should be based on good surveillance data and should give a high chance of therapeutic success, >95 percent. Surveillance programs mostly test a sample of gonococcal isolates each year using standard methods which detect emergence of resistance and drifts in susceptibility. There are a number of well established programs that have produced longitudinal data (Members of the Australian Gonococcal Surveillance Programme 1984; Schwarcz et al. 1990; Dillon 1992; Van de Laar et al. 1997) that inform therapy. In many parts of the world, penicillin is no longer suitable therapy and in recent years ciprofloxacin resistance has become widespread (WHO Western and Pacific Region Gonococcal Antimicrobial Surveillance Programme 2001).

However, most laboratories continue to test individual isolates on a daily basis in order to categorize strains as susceptible, exhibiting reduced susceptibility or resistance, particularly to the antibiotic used for therapy. Commonly used treatments include ciprofloxacin, ceftriaxone, and in some areas penicillin (or ampicillin). Routine susceptibility testing is largely performed using disc diffusion using a recommended method such as BSAC (British Society of Antimicrobial Chemotherapy) (King 2001) or NCCLS (National Committee for Control of Laboratory Standards 2003). The methods differ in the base medium and the disc content of antibiotic used, but if used according to the standard protocols and with appropriate controls, both give acceptable results. Problems can occur with susceptibility testing for *N. gonorrhoeae* because different strains vary in their nutritional requirements and growth rates, making comparison with control strains difficult. A quick and simple alternative is to use agar dilution breakpoints where growth or no growth is scored on agar plates incorporating one or two concentrations of antibiotic to categorize the isolates. It is a useful method for detecting high level resistance, for example, resistance to ciprofloxacin can be detected using a single concentra-

tion of 0.5 mg/l (minimum inhibitory concentration (MIC) $\geqslant$1 mg/l).

Antibiotic resistance

PENICILLIN

Penicillin or ampicillin was for many years the treatment of choice for gonorrhea until the emergence of chromosomal resistance due to continual usage of the antibiotic and the acquisition of plasmids from *Haemophilus* spp. Chromosomal resistance was the first to appear but was low level and initially responded to the use of increased dosage for treatment. Therapeutic failure due to chromosomally-mediated resistant *N. gonorrhoeae* (CMRNG) was reported in 1985 (Faruki et al. 1985) and became an increasing problem. Chromosomal resistance in *N. gonorrhoeae* is the result of additive effect of mutations at a number of loci including *penA*, *mtr*, *penB*, *penC*, and *ponA1* (Ropp et al. 2002), *penA* affects the affinity of penicillin for penicillin binding protein (PBP)2, *mtr* involves over expression of the efflux pump, *penB* is a mutation in the *por* gene, *ponA1* affects PBP1 and the function of *penC* is unknown. Together, mutations in these loci decrease the permeability of the cell wall, acting as a barrier to the penicillin.

In contrast, plasmid-mediated resistance was not detected until 1976, is enzyme-mediated and high level with a greater chance of therapeutic failure. In many countries the greatest prevalence was also in the 1980s but the prevalence remains high in some areas such as the Western Pacific, and penicillin cannot be used for therapy. Penicillinase-producing *N. gonorrhoeae* (PPNG) were first detected in infections acquired in Africa and Asia and were shown to be carrying plasmids of 3.2 and 4.4 MDa, respectively (Roberts 1989). These plasmids require the presence of a conjugative plasmid to transfer between gonococci and have now become disseminated worldwide. PPNG carrying plasmids of differing molecular weights have been isolated but have not spread so widely. All penicillinase plasmids in *N. gonorrhoeae* encode for the TEM-1 β-lactamase and differences in size reflect deletions in nonfunctional parts of the gene (Pagotto et al. 2000).

CIPROFLOXACIN

Ciprofloxacin, a fluoroquinolone, is an attractive alternative for the treatment of gonorrhea because it is given orally as a single dose, and hence compliance is good and can be observed. When ciprofloxacin was first introduced, *N. gonorrhoeae* were exquisitely sensitive and resistance was unknown. However, probably due to the misuse and overuse, particularly of the earlier generation of the quinolones, resistance due to mutations in the DNA gyrase gene, *gyrA*, and the topoisomerase IV gene, *parC*, has emerged (Knapp et al. 1997). High-level resistance (minimum inhibitory concentration (MIC) $\geqslant$1 mg/l) is due to multiple mutations in both *gyrA* and/or *parC* and may be enhanced by over expression of efflux systems and changes in the porin. Gonorrhea can be treated with other quinolones such as ofloxacin but *N. gonorrhoeae* exhibit cross-resistance between the quinolones and hence these are inactive against resistant strains. The newer quinolones such as moxifloxacin act primarily against *parC* and so are unlikely to be useful alternatives. Currently resistance to quinolones in *N. gonorrhoeae* is solely chromosomally mediated but reports of plasmid-mediated resistance in other organisms is worrying (Martinez-Martinez et al. 1998). Quinolone-resistant *N. gonorrhoeae* (QRNG) are most prevalent in the Western Pacific Region where the prevalence in some countries is above 50 percent. However, the prevalence of QRNG is increasing rapidly in countries in the western world such that ciprofloxacin is unlikely to remain an effective therapy for gonorrhea for very many more years.

CEPHALOSPORINS

Ceftriaxone, a third generation cephalosporin, is a recommended treatment for gonorrhea. It has proved highly active against *N. gonorrhoeae* including PPNG, and hence the original recommended dosage of 250 mg has been reduced to 125 mg in some guidelines (Centers for Disease Control and Prevention 2002a). Therapeutic resistance has not been documented although reduced susceptibility has been detected using in vitro susceptibility testing (Schwebke et al. 1995). This is of concern because cross-resistance has already been noted between cefuroxime, an earlier cephalosporin, and penicillin (Ison et al. 1990), particularly if lower dosages become common and usage increases because of resistance to other agents such as ciprofloxacin. Ceftriaxone is given by injection and some patients may prefer an oral third generation cephalosporin. However, data on efficacy and availability are still limited.

ALTERNATIVE TREATMENTS

Spectinomycin, 2 g intramuscularly, is still recommended as an alternative therapy for gonorrhea. Resistance has been documented and is single-step and high-level but it has occurred sporadically (Easmon et al. 1982; Boslego et al. 1987; Zenilman et al. 1987) and has not spread widely suggesting that it may be a suitable alternative. However, it has not been extensively used in recent years and has become difficult to obtain.

Azithromycin is used more commonly for chlamydial infection but has been suggested as an alternative for gonorrhea particularly when resistance to penicillin and ciprofloxacin is high. The recommended dosage is 2 g, but patients often find this difficult to tolerate and 1 g has been used (Young et al. 1997; Xia et al. 2000). However, resistance has been noted with both dosages

and increased usage is likely to increase the selective pressure.

Tetracycline is also more commonly used as treatment for chlamydial infection but has been used for gonorrhea where resources are limited. Resistance can be both chromosomal and low level (Johnson and Morse 1988) or plasmid-mediated and high-level (Morse et al. 1986). Plasmid-mediated resistance is due to the insertion of the *tetM* determinant, probably from streptococci, into the gonococcal conjugative plasmid, hence the plasmid can mobilize itself between gonococci and other genera. Since its first description in 1985 (Morse et al. 1986), tetracycline-resistant *N. gonorrhoeae* (TRNG) have spread widely, reducing its efficacy as an inexpensive alternative therapy.

Aminoglycosides such as gentamicin and kanamycin have been used in resource poor settings but information on resistance and relationship to in vitro susceptibility testing is lacking (Daly et al. 1997; Lkhamsuren et al. 2001). Co-trimoxazole is also used but the true prevalence of resistance is difficult to determine because of the difficulties in susceptibility testing (West et al. 1995).

Typing

Techniques used to discriminate between strains of *N. gonorrhoeae* from different sources have been used to monitor temporal changes, detect clusters of antibiotic resistant strains, and confirm or dispute contact, largely in cases of child or sexual abuse. Phenotypic methods of auxotyping, differentiation by nutritional requirement (Catlin 1973) and serotyping, reactivity with a panel of monoclonal antibodies directed at specific epitopes on Por, the major outer membrane protein (Knapp et al. 1984), have been used extensively for these purposes. However, these tests lacked discriminatory power and even when used in combination, a few auxotype/serovar classes predominate in most populations. Both auxotyping and serotyping had subjective endpoints presenting some problems of reproducibility, particularly in longitudinal studies. In recent years a range of molecular techniques have been described, all of which have enhanced discriminatory ability compared to the phenotypic methods (Ison 1998). However, many of the techniques examine variation in genes that are exposed to the immune response and hence are subject to greater diversity. While this approach does not give valuable information for studies over long time periods, where change is likely to occur through genetic exchange in mixed infections, it is more useful for identifying sexual contacts, short chains of transmission, and for studying sexual networks (Ward et al. 2000). There is increasing interest in using a molecular approach to identifying clusters of isolates from linked patients to aid public health interventions. Combined studies using epidemiological and molecular data suggest that molecular typing will identify clusters that are larger than clusters identified by epidemiological information alone, which may give useful data to clinicians if used prospectively.

TREPONEMA PALLIDUM

Treponema pallidum subsp. *pallidum* is the causative agent of syphilis, a mucocutaneous infection, which is highly infectious in the early stages and has serious sequelae if left untreated. The primary stage of syphilis usually presents as a painless ulcer, which occurs 9–90 days after exposure, and may be accompanied by a regional lymphadenopathy. The secondary stage has many symptoms including localized or diffuse ulcers, generalized lymphadenopathy, rash, and condylomata lata and presents 6 weeks to 6 months after exposure. Latent syphilis, by definition, has no clinical signs but gives a positive serological reaction and is present either less than (early) or more than (late) 2 years after exposure. Tertiary syphilis is rare when good antibiotic therapy is available but can include gummatous syphilis, neurosyphilis, and cardovascular syphilis.

T. pallidum is a spirochete of approximately 0.2 μm in diameter and 5–15 μm in length. It is an obligate human pathogen and has never been grown successfully on artificial media, the only successful cultivation being in rabbits. The cell envelope structure is unique and unlike other gram-negative organisms, it has an outer membrane, but lacks lipopolysaccharide and porins have not been detected. The organism possesses flagella, for motility, which are located in the periplasmic space instead of externally as is normally found in motile bacteria. It has a very restricted temperature range for growth, 30–35°C, and in rabbits the generation time has been demonstrated as 35 h. The complete genome sequence is known (Fraser et al. 1998) and the genome is determined to be 1.14 Mb, approximately 25 percent of the size of the *E. coli* genome, and encodes for 1040 genes or open reading frames.

Epidemiology

Syphilis is a worldwide public health problem (Gerbase et al. 1998). It is a major cause of genital ulcer disease in the developing world and the prevalence is high in the newly independent states of the former Soviet Union and is a concern because of the strong association with the acquisition of HIV infection. After a peak in incidence following World War II there was a decline in many countries, particularly in the industrialized world, and syphilis became largely a disease of men who have sex with men. Following the advent of AIDS in 1984 and subsequent changes in sexual behaviour, syphilis declined. In the United States there were efforts to eliminate syphilis. In recent years there have been an

increasing numbers of outbreaks of syphilis reported in the USA and many countries in Europe (Doherty et al. 2002). Many of the outbreaks are among men who have sex with men, possibly reflecting an increase in risk behaviour following a perception that HIV infection is now a treatable infection. Penicillin is the mainstay of treatment for all stages of syphilis infection (Centers for Disease Control and Prevention 2002a)

Diagnosis

MICROSCOPY

Examination of lesion exudate or lymph nodes by dark-ground microscopy is a useful presumptive diagnostic tool for infectious (primary) syphilis. However, it should be performed by experienced workers because of the interference with commensal spirochetes that are found as part of the normal flora of the genital and gastro-intestinal tract. It is not considered as suitable for use with rectal or nongenital lesions and is not recommended for oral lesions.

Exudate from the syphilitic ulcer should be collected after cleansing of the ulcer with sterile saline using a gauze swab. The ulcer should then be squeezed to allow sufficient serous fluid to be produced and then this should be collected by a loop and placed onto a microscope slide. It is not necessary to add any saline to the microscope slide. After placing a coverslip onto the fluid it should be examined by dark ground microscopy within 10 min in order to identify the characteristic morphology and motility of *T. pallidum*. If the initial examination is negative, this test can be repeated daily for at least 3 days as long as antibiotics are not given.

SEROLOGICAL DIAGNOSIS

The inability to cultivate *T. pallidum* has led to the use of the detection of the host's immune response as an indicator of exposure to infection. Serological tests for syphilis can be divided into screening tests and confirmatory tests. Historically screening tests employed nontreponemal antigen, which detects antilipoidal antibodies that are produced in response to the tissue damage caused by treponemal diseases including syphilis but also other unrelated diseases, whereas confirmatory tests use a specific treponemal antigen. However, the development of enzyme immunoassays using specific antigen that are automated and can be used to screen large numbers has in some instances replaced the nontreponemal tests for screening.

NONTREPONEMAL TESTS

The nontreponemal tests using the Venereal Disease Research Laboratory (VDRL) antigen, whose main components are cardiolipin, cholesterol, and lecithin, have been widely used for screening for syphilis. Plasma is mixed with the VDRL antigen and if antibody is present flocculation results which can be read microscopically (VDRL test) or macroscopically (Rapid Plasma Reagin (RPR) test), which is applicable for use in resource poor settings with little or no laboratory facilities. The tests differ in the particle size used and the pigment used to enhance visualization of the result. These tests are mostly used qualitatively but if used quantitatively can give a measure of the response to therapy. False positive results do occur, for instance during pregnancy or with autoimmune disease, such that all positive results should be confirmed using a specific treponemal test.

SPECIFIC TREPONEMAL TESTS

Enzyme immunoassays (EIA) using specific treponemal antigen, which has been cloned or sonicated and adsorbed onto a solid phase, are a relatively new approach to detection of antibody in syphilis. The EIAs can detect both IgG and/or IgM but those that detect IgG and IgM together are recommended because they tend to be more sensitive in primary infection (Schmidt et al. 2000). The *T. pallidum* particle assay (TPPA) and the *T. pallidum* haemagglutination assay (TPHA) both utilize a specific antigen which is attached to gelatin beads (TPPA) or erythrocytes (TPHA). The fluorescent-treponemal antibody-absorbed (FTA-ABS) test is an indirect immunofluorescence test which detects antibody that attaches to treponemes coating a microscope slide and the resulting antigen–antibody complexes are detected by a secondary antibody linked to a fluorochrome. The TPHA and TPPA have been widely used as screening and confirmatory tests, although the TPPA has been shown to be more sensitive than the TPHA in primary syphilis. The EIA is attractive because it has the capacity to screen large numbers using a specific antigen in an automated system. The TPHA/TPPA can be used to confirm a positive EIA result and vice versa. The FTA-ABS test is more time consuming and used mostly to confirm discrepant results between other tests. An additional test often used in research laboratories is based on immunoblotting to detect antibody to recombinant antigens. This test has a sensitivity similar to the FTA-ABS test. The choice of screening and confirmatory tests is dependent on workload and facilities available and will differ considerably dependent on the resources available.

HAEMOPHILUS DUCREYI

Haemophilus ducreyi is a fastidious organism which is the causative agent of the sexually transmitted disease, chancroid. It presents primarily as a genital ulcer but can also present as a regional lymphadenopathy with bubo formation. *H. ducreyi* is thought to establish itself through small abrasions, which may occur in the epidermis during sexual intercourse. Once colonization has been achieved, a small papule develops after a short

incubation period of 5–10 days, which may progress to form an ulcer. The ulcers are painful and have ragged and undermined edges, and can persist for many months in the absence of antibiotic therapy. Lesions usually occur on the prepuce and frenulum of men and the vulva, cervix, and perianal region in women. Extragenital chancroid is rare but lesions have been reported on the inner thighs, breasts, and fingers (Lewis 2000). Unlike other sexually transmitted infections, chancroid has few sequelae and has largely been considered a treatable infection. However, the strong association of chancroid, together with syphilis, with the acquisition of the human immunodeficiency virus (HIV) has renewed interest both in providing good diagnostic tests and research studies. This has become more important with the studies which have suggested that aggressive treatment of bacterial sexually transmitted infections (STI), such as chancorid, can reduce the acquisition of HIV (Grosskurth et al. 1995).

Chancroid is one of the most common STIs but is found predominantly in the Tropics and found only occasionally in North America and Europe (Trees and Morse 1995). Chancroid is more common in men than women and there is considerable debate over whether asymptomatic carriage occurs in women, which is largely unresolved. The high prevalence in resource-poor settings raises challenges for diagnosis as good laboratory facilities are often unavailable. Isolation of *H. ducreyi* is still regarded as the gold standard, if available, because microscopy is nonspecific and molecular methods are not commercially available. However, in resource poor settings diagnosis is usually made on the clinical symptoms and signs and treated syndromically.

Isolation of *H. ducreyi*

It is possible to cultivate *H. ducreyi* but it is a fastidious organism that requires a highly nutritious medium. It also appears that different strains of *H. ducreyi* appear to grow preferentially on some culture media, particularly on primary isolation, and so the highest isolation rates (approximately 80 percent) have used multiple media. Two culture media, which include serum, that have been used are GC agar base supplemented with 1 percent hemoglobin, 5 percent fetal calf serum, and 1 percent IsoVitaleX and Mueller–Hinton agar supplemented with 5 percent chocolatized horse blood and 1 percent IsoVitaleX (Dangor et al. 1992). A serum free medium which is less expensive to prepare, which has been used successfully, contains GC agar supplemented with 1 percent hemoglobin, 0.2 percent charcoal, and 1 percent IsoVitaleX (Lockett et al. 1991). Selective agents to inhibit the growth of skin organisms, particularly gram-positive cocci, and allow the growth of *H. ducreyi* have been difficult to choose, but 3 mg/l of vancomycin is usually added.

Isolation of *H. ducreyi* appears most successful if the ulcer is cleaned with a cotton swab to remove superficial pus and the material taken from the undermined edge of the ulcer and inoculated directly from the patient onto the culture medium. Primary isolation media should be incubated at 33°C for optimal growth condition in high humidity with 5 percent carbon dioxide for a minimum of 48–72 h before being discarded as negative. There is no transport medium that has been widely tested although some success has been demonstrated using a thioglycollate-hemin-based medium (Dangor et al. 1993).

After incubation, gray translucent colonies will appear which are gram-negative cocco-bacilli and weakly oxidase positive. The most characteristic sign is friable colonies that can easily be pushed around the plate. These three criteria are highly predictive of *H. ducreyi*, and in most instances no further identification is performed.

Microscopy

Microscopy is often used in clinical settings for the presumptive diagnosis of an STI but has proved poorly specific for the diagnosis of chancroid. The gram-negative cocco-bacilli are described as appearing in sheets, which resemble 'schools of fish' or 'railroad tracks' but this can be very difficult to detect in clinical specimens direct from the patient and is not recommended for the routine diagnosis (Albritton 1989).

Molecular detection

Commercial tests for the molecular detection of *H. ducreyi* are not widely available. However, a multiplex polymerase chain reaction (PCR) assay has been evaluated which gives the simultaneous amplification of DNA from *H. ducreyi*, *T. pallidum*, and herpes simplex virus types 1 and 2 which is more sensitive than existing methods (Orle et al. 1996). Comparison between multiplex-PCR and culture has shown the sensitivity of culture for *H. ducreyi* to be around 75 percent but this is dependent on good isolation procedures and has been less in some studies (Orle et al. 1996; Morse et al. 1997).

Antimicrobial resistance and therapy

H. ducreyi are innately sensitive to most antibiotics but, in a similar manner to *N. gonorrhoeae*, have become resistant to many antimicrobial agents through the acquisition of plasmids or selection of chromosomal mutations. Plasmid-mediated resistance has been reported to tetracycline, chloramphenicol, sulphonamides, aminoglycosides, and β-lactam antibiotics. Chromosomal resistance is less well documented but decreased susceptibilities to trimethoprim, penicillin,

ciprofloxacin, and ofloxacin have been reported (Trees and Morse 1995; Lewis 2000).

Despite the emergence of resistance over the last decade, chancroid is still treatable. Azithromycin, ciprofloxacin, erythromycin, and ceftriaxone form part of the recommendations for treatment from the Centers for Disease Control and Prevention and from the World Health Organization, although the dosage and regimens differ slightly.

Susceptibility testing

Testing the susceptibility of *H. ducreyi* can be difficult because of the fastidious nature of the organism and its tendency to adhere to the agar. Most studies have used agar dilution rather than disc diffusion and have been performed in specialist centers. A prerequisite for susceptibility testing is a viable organism and only a limited number of centers have routine culture established and hence the antibiogram of many strains is not tested. A standardized method has been recommended for determination of the MIC which includes, standardization of the inoculum, use of enriched Mueller–Hinton agar containing a range of antibiotic concentrations, incubation at 35°C in a humid atmosphere containing 5 percent carbon dioxide, and examination of the result after 48 h of incubation (Dangor et al. 1990).

KLEBSIELLA (CALYMMATOBACTERIUM) GRANULOMATIS

K. granulomatosis is a gram-negative bacillus which is the causative agent of donovanosis, which usually presents as genital ulceration but may also be oral or found at extra-genital sites. Genital ulceration is often associated with inguinal lymphadenopathy and if left untreated considerable tissue destruction can occur. Donovanosis is largely considered a tropical disease having not been reported in Europe and the USA although its true prevalence is unknown.

K. granulomatis has been included in several genera and was for a long time called *Calymmatobacterium granulomatis*. However, its similarity with *Klebsiella* species, originally detected using serology (Goldberg 1962) and ultrastructural studies (Kuberski et al. 1980) has been confirmed by molecular studies and the name change to *K. granulomatis* (Carter et al. 1999) proposed, although it remains controversial (Kharsany et al. 1999).

Culture of the organism in vitro is difficult and was originally performed in the yolk sacs of chick embryos but more recently in human peripheral blood mononuclear cells (Kharsany et al. 1997) and in Hep-2 cells (Carter et al. 1997). However, diagnosis is rarely made by culture but usually by the examination of smears stained using a Giemsa or related stain for the characterisitic donovan bodies or more recently by a newly described nucleic amplification test (Carter and Kemp 2000). The lack of a culture has prevented studies on susceptibility to antibiotics although a range have been used for treatment including ampicillin, chloramphenicol, and ceftraixone.

BACTERIAL VAGINOSIS

Gardnerella vaginalis, *Prevotella* spp., *Peptostreptococci*, the anaerobic curved rods, *Mobiluncus* spp. and *Mycoplasma hominis* are closely associated with the syndrome known as bacterial vaginosis (BV) which is characterized by a change in vaginal ecology. These organisms can be found in the 'normal' vagina but in small numbers, which in BV multiply and increase 100–1000 fold to become the predominant flora. These large numbers of bacteria adhere to squamous epithelial cells giving them a studded appearance that led to them being described as 'clue cells', as an indicator of the condition. The pH of the vaginal fluid also increases from below 4.5 to 5.0 or greater. This is almost certainly maintained by the large numbers of bacteria associated with BV that produce amines, but it is unclear which occurs first, the rise in pH or the increase in bacterial numbers. BV was previously known as 'non-specific vaginitis' or *Haemophilus vaginalis* vaginitis (Gardner and Dukes 1955) but in 1983 the term bacterial vaginosis became popular as it reflected the strong association with overgrowth of certain bacteria and the absence of an inflammatory response. Other terms which are commonly used are anaerobic vaginosis and Gardnerella vaginosis or vaginitis.

BV is the commonest cause of vaginal discharge of women of child-bearing years in the western world. BV is a clinical syndrome which presents as an increased vaginal discharge which has a distinctive fishy smell which is often reported as worse after sexual intercourse. The true prevalence is probably unknown but has been reported as being 10–20 percent of sexually active women (Hay et al. 1992). Predisposing factors for BV have been difficult to identify but of the many investigated, the association with sexual activity is the strongest. This is supported by a higher prevalence in sexually active women including those attending specialized clinics for sexually transmitted diseases or for termination of pregnancy (Blackwell et al. 1993). It has also been found to be more common among women using intra-uterine contraceptive devices (Amsel et al. 1983) and in a number of studies among lesbian women (Berger et al. 1995; Skinner et al. 1996). It is generally considered to be a sexually associated condition rather than sexually transmitted. This is supported by its presence in some virgin girls (Bump and Buesching 1988), its high prevalence in lesbian women who have a low incidence of sexually transmitted infections, and the failure to prevent recurrent episodes after treatment of sexual partners (Colli et al. 1997).

G. vaginalis was the first bacterium to be associated with the syndrome of BV, but it became clear in the 1970s, with the improvement of cultural techniques, that a more complex bacterial flora existed including anaerobes and *M. hominis*. It was not until 1984 that *Mobiluncus*, anaerobic curved rods, were described (Spiegel and Roberts 1984) and consists of two species, *Mobiluncus curtisii* and *Mobiluncus mulieris*. *M. curtisii* are small curved rods which are gram-variable and are divided into two subspecies, *M. curtisii* subsp. *curtisii* and *M. curtisii* subsp *holmesii*. *M. mulieris* is a longer curved rod which is gram-negative. Anaerobic curved rods show a strong association with BV with few women without vaginosis apparently being colonized. However, *Mobiluncus* spp. are very difficult to cultivate and more sensitive nucleic acid amplification methods have shown that although a strong association with BV exists, more women without BV are colonized than previously found (Schwebke and Lawing 2001). The strong association between colonization with *Mobiluncus* spp. and BV has led to the hypothesis that they may represent a separate syndrome, but no evidence exists for this.

Diagnosis

For many years a variety of methods were used for the diagnosis of BV, many of which arose from the original description of the condition by Gardner and Dukes (1955). Recognition of the clinical signs and symptoms, presence of 'clue cells' in a wet mount of vaginal discharge, and isolation of *G. vaginalis* were among the methods used. These methods were unsatisfactory because reporting of signs and symptoms is subjective and varies between patients and while 'clue cells' and *G. vaginalis* are good markers for BV they can also be present in small numbers in women without BV.

Since 1983, the accepted standard for the diagnosis of BV has been the use of four composite criteria (Amsel et al. 1983); a thin homogeneous vaginal discharge, elevated vaginal pH, presence of amines detected by a fishy smell on the addition of potassium hydroxide to the discharge, and the presence of 'clue cells'. If three or more of the four criteria are present then the patient is diagnosed with BV, if less than three are detected the patient is considered not to have BV or to be 'normal'. These criteria have formed the basis of the diagnosis of BV for nearly two decades because they are simple to perform, particularly in a clinic or consultation room, and require minimal material with the exception of a microscope. However, the composite or Amsel's criteria do have some disadvantages as they require a vaginal examination and recognition of the vaginal discharge and 'fishy' smell have a subjective endpoint. There has also been a tendency to use only one or at least not all four criteria, hence invalidating the method. Each of the individual criteria are predictive of BV but do not have the same sensitivity and specificity as when they are used in combination.

An alternative approach for diagnosis is the grading or scoring of the Gram stained vaginal smears to detect the change in vaginal ecology and the strong bacterial associations. The method first described divided smears into those with a predominantly *Lactobacillus* morphotype, which was considered normal, and those with a mixed microbial flora and no lactobacilli, which were graded as BV (Spiegel et al. 1983). This initial method was modified to include an intermediate category, where the smears showed a predominantly mixed microbial flora but had significant numbers of lactobacilli (Nugent et al. 1991). These methods quantify the numbers of different morphotypes of bacteria, lactobacilli, *Gardnerella*/*Bacteroides*, and *Mobiluncus*, assign a score for each which when combined gives a number which defines the grading. These methods have been used extensively for research studies and have given valuable data but they require considerable time and skill, which is not always available in clinical or diagnostic situations. Simpler methods have been described where the microbial flora is assessed qualitatively and graded into normal, intermediate or BV (Thomason et al. 1992; Hay et al. 1994). Both the quantitative and qualitative methods have been validated in comparison with the composite criteria and found to have a high sensitivity, specificity, and predictive values for the definition of 'normal' and 'BV' (Schwebke et al. 1996; Thomason et al. 1992; Ison and Hay 2002). However, the inclusion of the intermediate category with BV reduces the specificity and is more frequent in women defined as normal by the composite criteria (Ison and Hay 2002; Taylor-Robinson et al. 2003). This suggests that the vaginal flora associated with the intermediate grade is distinct from that of BV and does not equate with the full clinical syndrome of BV and hence cannot be diagnosed by clinical criteria. A recommended grading system is shown in Table 3 and Figure 1.

Treatment

In the absence of a clear causative agent, the treatment for BV is primarily aimed at the eradication of the bacteria associated with the clinical condition in an attempt to re-establish the normal 'lactobacillary' flora. The inadequacy of antimicrobial agents to effect a cure is highlighted by the high relapse rates but alternative approaches using replacement flora (bacteriotherapy) are not yet widely available.

Metronidazole is the agent of choice by many clinicians and is given either as a 5 day course of 400 mg twice a day or as a single dose, 2 g. The 5 day course may give a slightly higher cure rate but metronidazole causes nausea and the single dose has a higher compliance rate. Topical gels have been used increasingly and

Table 3 *Grading scheme for Gram-stained vaginal smears (Ison and Hay 2002)*

Grade of flora	Definition of flora	Description
0	Normal[a]	Epithelial cells only – no bacteria seen
I	Normal	Lactobacillus morphotype only
II	Intermediate	Reduced lactobacillus morphotype with mixed bacterial flora
III	Bacterial vaginosis	Mixed bacterial flora with few or absent lactobacillus morphotype
IV	Normal in asymptomatic women[b]	Epithelial cells covered with gram-positive cocci with few or absent lactobacillus morphotype

a) Normally found during or immediately post antibiotic therapy.
b) May be a cause of aerobic vaginitis or be of importance in pregnant women.

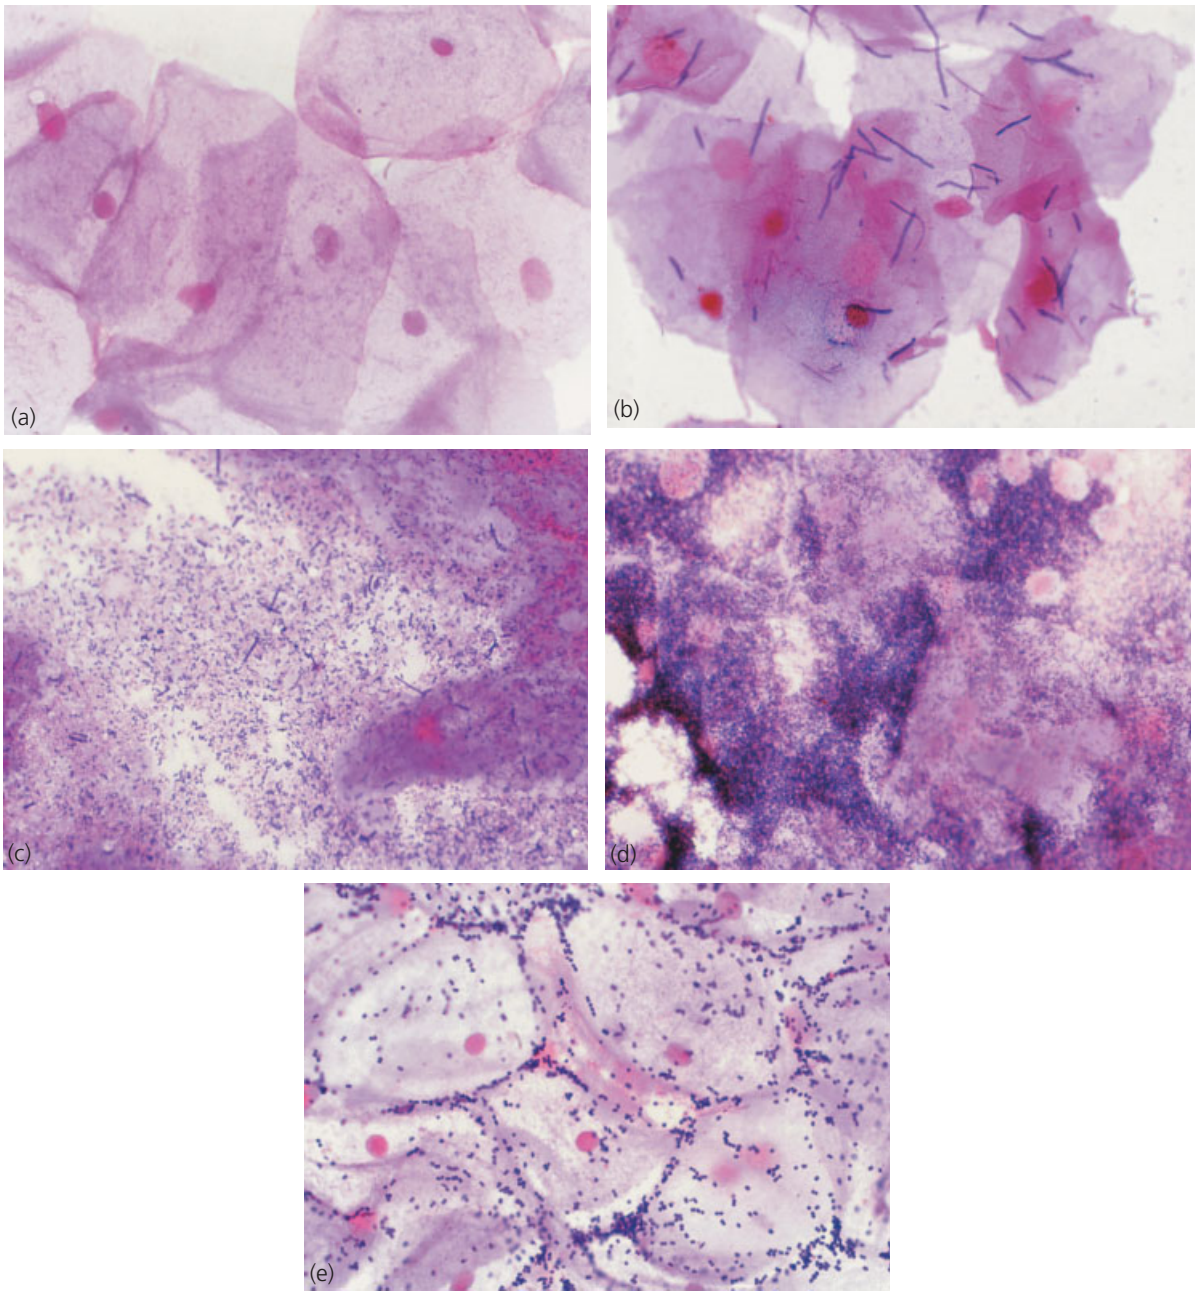

Figure 1 *Examples of grading for Gram stained vaginal smears,* **(a)** *Grade 0,* **(b)** *Grade I,* **(c)** *Grade II,* **(d)** *Grade III, and* **(e)** *Grade IV.*

offer a more acceptable alternative particularly for women with recurrent episodes or for pregnant women. Two agents are widely available, clindamycin 2 percent cream, which is applied twice a day for 7 days or a metronidazole gel, 0.75 percent. Clindamycin is active against lactobacilli and hence it takes a few days for them to re-establish in the vagina. Cure rates with topical treatment are similar to the oral treatment (Hay 1998). An attractive approach is the use of lactobacilli as a probiotic, and has been tried with H_2O_2 producing lactobacilli, but has not been proven to be successful (Hallen et al. 1992) and is not widely available. Treatment of male partners does not appear to improve relapse rates even in double-blind, placebo-controlled trials. Unfortunately, for many women, antimicrobial therapy only offers a short term resolution and recurrence is common with all treatments and probably reflects our ignorance at the underlying cause of BV.

Sequelae

For many years BV was considered a mild if unpleasant condition which had no sequelae and was often not taken seriously as a clinical entity. However, there is now strong evidence that BV is associated with complications in both pregnant and nonpregnant women. Women with BV who are pregnant have an increased risk of late miscarriage and preterm birth (Hay et al. 1994; Hillier et al. 1995), with women at greatest risk being those who have had a previous preterm birth. Complications, such as endometritis, are also more common among women with BV (Watts et al. 1990; Soper 1993; Persson et al. 1996).

STREPTOCOCCUS AGALACTIAE

S. agalactiae (group B streptococci) are known to colonize the vagina of some women, although the prevalence varies between 10–40 percent in different studies (Honig et al. 2002; Bayo et al. 2002). It has generally been regarded as part of the normal flora but its role in vaginitis is unclear. Group B streptococci have been isolated from women with symptoms and it has been suggested as a cause of aerobic vaginitis (Maniatis et al. 1996; Donder et al. 2002) with characteristics distinct from BV (Donder et al. 2002). Its importance lies in its ability to cause neonatal infection, particularly meningitis, which can be acquired from the mother during passage through the birth canal. Of neonates that are colonized, 1–3 percent develop disease caused by group B streptococci, mostly early-onset infection within 24 h of birth. Intervention of vaginal colonization during pregnancy has been found to be ineffective but introduction of guidelines for screening of vaginal and rectal swabs in 1996 at 35–37 weeks gestation followed by treatment of colonized women has reduced incidence (Schrag et al. 2002).

Isolation and identification

Group B streptococci grow easily on enriched culture medium such as blood agar, producing reasonably large colonies and a diffuse β-hemolysis. In women who are colonized, group B stretococci are often found in large numbers, but for screening purposes and for detection of small numbers in mixed cultures, selective media can be useful, blood agar with neomycin (30 mg/l) and nalidixic acid (15 mg/l), neomycin nalidixic acid (NNA) agar or colistin (10 mg/l) and nalidixic acid (10 mg/l), colistin nalixidic acid (CNA) agar. NNA has been reported to be more sensitive than CNA (Dunne 1999). Some studies favor prior incubation in enrichment broth, Todd–Hewitt broth supplemented with 15 mg/l nalidixic acid and 8 mg/l gentamicin, to achieve maximum identification of carriers (Dunne and Holland-Staley 1998; Votava et al. 2001). Detection of group B streptococci using rapid immunological methods such as latex agglutination have only proved useful for specimens from heavily colonized women. However, recent development of real-time PCR has proved a possible alternative to culture (Ke and Bergeron 2001).

Commercial kits, that have good quality control and rarely give false positives, are available for serogrouping β-hemolytic colonies. Other tests for identifying group B streptococci include inoculation of media containing starch and horse serum, which produce a distinctive orange pigment after incubation (Islam 1977), and the Christie–Atkins–Munch-Petersen (CAMP) test, where group B streptococci produce a diffusible extracellular protein (CAMP factor) that acts synergistically with staphylococcal beta-lysin to enhance lysis of red cells, and hydrolysis of sodium hippurate.

Treatment

Treatment of nonpregnant women colonized with group B streptococci who do not have symptoms is not considered necessary. Group B streptococci are not known to be resistant to penicillin and this remains the treatment of choice, if required. Prophylaxis with penicillin is recommended in women colonized when screened at 35–37 weeks gestation. Ampicillin can be used as an alternative (Centers for Disease Control and Prevention 2002b).

STAPHYLOCOCCUS AUREUS

Colonization of the vagina by *S. aureus* is relatively unusual but in menstruating young women, often associated with tampon use, has been linked to toxic shock syndrome. The syndrome presents as an acute febrile illness resulting in shock and organ failure and requires rapid diagnosis for successful treatment. It is caused by *S. aureus* that produce a number of toxins including

toxic-shock syndrome toxin-1 (TSST-1) which can be detected using radio-immunoassays, immunoassays or reverse passive latex agglutination tests.

OTHER BACTERIAL CAUSES OF GENITAL TRACT INFECTIONS

There are a few bacteria that cause infections of the genital tract that are encountered relatively rarely. *Listeria monocytogenes*, which can cause infection in pregnant women and lead to serious infection such as septicemia, may affect the fetus, resulting in stillbirth or neonatal meningitis. It is not routine practice to screen vaginal swabs for *L. monocytogenes* but blood cultures should be taken if clinically indicated. *Actinomyces* spp. are occasionally encountered associated with infections related to the presence of an intrauterine device and *Clostridium perfringens* has been a common cause of infection following delivery of gynecological surgery, which has largely been controlled by good surgical practice.

Mycoplasma spp. are commonly found in the genital tract, particularly *M. hominis*, and their role in infection has been debated. However, *M. hominis* is considered a cause of pelvic inflammatory disease and *M. genitalium* is associated with urethritis in men (see Mycoplasma).

Bacterial infections of the urinary tract

SÖREN G. GATERMANN

Anatomical considerations	1	The physiological flora of the urinary tract	6
Host defense mechanisms	1	Diagnosis	6
Clinical syndromes	2	Management of urinary tract infections	8
Microbiology of urinary tract infections	3	References	9
Pathogenesis	3		

Urinary tract infections are amongst the most common infections encountered in clinical practice. About 50 percent of all women experience at least one episode of urinary tract infection during their lifetime. In women, the incidence of symptomatic infections increases with age. In men, urinary tract infections tend to occur more often in young boys or elderly persons and homosexuals. Symptomatic urinary tract infections are characterized by symptoms like dysuria, urgency, painful and frequent voiding, accompanied by the presence of bacteria in the normally sterile urine. Apart from symptomatic infections, there is a condition called asymptomatic bacteriuria that is characterized by the presence of bacteria in the urine but the lack of clinical symptoms. This condition may be a predisposition for symptomatic infection.

It is of utmost importance to distinguish between so-called uncomplicated urinary tract infections, which are characterized by the absence of functional or anatomical obstacles to urinary flow, and complicated urinary tract infections in which such obstacles are present, because patients with complicated urinary tract infections more often develop urosepsis and renal damage and bear a higher mortality. In addition, in complicated urinary tract infections the infecting organisms tend to be less susceptible to antimicrobial drugs.

Urinary tract infections encompass a wide array of clinical entities such as urethritis, cystitis, pyelonephritis, epididymitis, prostatitis, and perinephritic abscess. Most commonly, infections affect the bladder, urethra, and kidney.

ANATOMICAL CONSIDERATIONS

The epithelia of the urinary tract are bathed in a constant flow of urine originating in the kidneys, flowing via both ureters into the bladder where the fluid accumulates until it is voided at intervals via the urethra. Normally, only a minute residual volume of urine remains within the urinary tract after voiding. Anatomical or functional obstacles to urinary flow may cause an increased volume of urine to be retained within the urinary tract. If such residual volume does contain bacteria, the organisms may multiply, attain high bacterial densities, and ultimately, damage the epithelial surface causing an immune response and symptoms. The pressure in the bladder is increased during voiding and reflux into the ureters is normally avoided by the oblique insertion of the ureter into the bladder wall, providing an efficient valve mechanism. Reflux into the kidneys may cause renal scarring and malfunction. A number of conditions may lead to an increased residual urinary volume. These can be pathological conditions that impair voiding such as an enlarged prostate in men, urinary stones, or tumors, as well as neurological or functional conditions such as the neurogenic bladder present in spinal cord injury, multiple sclerosis or cerebrovascular accidents, or the atonic bladder of diabetics.

HOST DEFENSE MECHANISMS

The constant urinary flow and the low residual volume are major factors that counteract bacterial colonization.

In addition, the urine contains protective factors such as immunoglobulins that may interfere with bacterial colonization. Also high concentrations of urea are inhibitory to bacterial growth.

The kidneys produce and secrete a protein, the Tamm–Horsefall protein, which acts as a receptor for bacterial adhesins thus trapping the invading organisms before they reach their cellular targets (Leeker et al. 1997; Pak et al. 2001). It has also been shown that bacterial adhesion to uroepithelial cells causes cells to exfoliate and thus effectively expell the more invasive organisms (Kunin et al. 2002). In addition, adhesion to and invasion of urothelial cells triggers secretion of IL8 which is a signal for transmigration of leukocytes into the urinary tract (Frendéus et al. 2000).

It is known that the distal portion of the female urethra is colonized by bacteria. Colonization becomes less dense in the proximal portions. Several studies have shown that the slope of the curve representing the bacterial counts in different portions of the urethra is steeper in women who do not suffer from recurrent urinary tract infection (UTI) compared to those who do (reviewed in Kunin et al. 2002), suggesting that the urethra has an important function in preventing UTI. The epithelium of the urethra responds to hormonal influences like the vaginal epithelium.

An important defense mechanism is the secretion of blood group antigens that may function as receptors for bacterial attachment. It has been shown that women suffering from recurrent urinary tract infections more frequently do not secrete Lewis blood group antigens than controls (Sheinfeld et al. 1989; Raz et al. 2000).

CLINICAL SYNDROMES

Acute cystitis

Cystitis is the most common presentation of urinary tract infection. It is characterized by dysuria, increased frequency and urgency of voiding, suprapubic discomfort, and a cloudy urine. The condition is far more common in women than in men. In some women, cystitis may be associated with sexual activity (Remis et al. 1987), the use of contraceptive diaphragms (Latham et al. 1985), or spermicides. About one-third of women with cystitis experience a recurrence of the infection.

Urethral syndrome

A striking proportion of women (30–50 percent) who present with symptoms suggestive of a urinary tract infection do not have significant bacteriuria (O'Grady et al. 1970). In some patients the bladder urine obtained by suprapubic aspiration shows that some of these women have cystitis with a low bacterial count, but in the remainder the urine is sterile (Stamm et al. 1980). Various microbial and nonmicrobial etiologies have been suggested to be responsible for the syndrome in these patients. Since the first episodes of urethral syndrome and acute cystitis are virtually indistinguishable in clinical practice, antimicrobial therapy is recommended for both conditions (Baerheim et al. 1999).

Acute pyelonephritis

Patients with acute pyelonephritis often present with loin pain, fever, and a positive urine culture. The microbial spectrum is similar to that of acute cystitis. Acute pyelonephritis is a common complication in pregnant women with previously untreated asymptomatic bacteriuria. In patients with diabetes, upper urinary tract infection is common (Patterson and Andriole 1997) and severe complications such as necrotizing papillitis may occur.

Other infections

Renal abscess is a hematogenous infection most often caused by *S. aureus*. The lesion is localized in the renal cortex and urine culture may be negative even in the presence of pyuria. *Enterobacteria* only rarely cause renal infections via the hematogenous route.

Perinephric abscess does not involve the renal parenchyma, but it may complicate acute pyelonephritis, in which case the causative pathogen derives from the urinary tract.

Acute prostatitis is most often caused by the same spectrum of microorganisms that is resposible for acute cystitis. In chronic prostatitis, bacteria often cannot be isolated by conventional techniques, but the symptoms and the presence of leukocytes suggests infection. In a molecular study, Krieger et al. have found the DNA of fastidious and rarely isolated species in the prostatic fluid of such patients (Krieger et al. 1996). As other authors (Lee et al. 2003) did not find differences of bacterial colonization between men with and without prostatitis, it is unclear at present how the results of Krieger et al. should be interpreted.

Urinary tract infections in special hosts

Diabetics are reported to have a somewhat higher prevalence of asymptomatic bacteriuria. They may also suffer from a nerve dysfunction leading to a lower voiding frequency and an increased residual urinary volume (Patterson and Andriole 1997; Zhanel et al. 1991).

Urinary tract infections in solid organ transplant patients tend to occur more often during the first few months after transplantation, especially after renal transplantation (Muñoz 2001; Takai et al. 1998).

MICROBIOLOGY OF URINARY TRACT INFECTIONS

The vast majority of urinary tract infections is caused by a single organism from a very limited spectrum of bacteria. In uncomplicated cystitis, the organism is almost always *Escherichia coli* or *Staphylococcus saprophyticus*, whereas in complicated cases, the spectrum is more diverse, encompassing several Enterobacteriaceae and gram-positive microorganisms such as enterococci (Table 1). Polymicrobial infections occur virtually exclusively in complicated cases, especially in patients with chronic indwelling catheters. Pyelonephritis is most often caused by *E. coli*, but *Proteus mirabilis* may also be encountered.

Many other species are infrequently or only rarely found (Bottone et al. 1998; Bézian et al. 1990; Cappelli et al. 1999; Fraimow et al. 1994; Funke et al. 1998; Janda et al. 1993; Morgan and Hamilton-Miller 1990; Salahuddin et al. 1996; Snehalatha et al. 1992; Stewart et al. 1993; Sturm 1989; Wong and Yuen 1995). If an infection with an unusual organism is suspected, etiology can be confirmed by repeated culture and/or suprapubic aspiration. However, as most microbiologists only expect the usual bacteria, fastidious or difficult-to-identify bacteria may be overlooked.

In nosocomial infections, gram-positive cocci, especially enterococci are the second most commonly isolated species (Table 1). It is not always clear whether an isolate represents a true pathogen or is merely contamination with an organism selected by chemotherapy. However, urinary tract infections with enterococci are a predisposition for the development of enterococcal bacteremia (Maki and Agger 1988).

PATHOGENESIS

Most often the infecting microorganisms ascend via the urethra into the bladder. Of course, their invasion may be facilitated by the presence of devices such as urinary catheters. Before the bacteria ascend they usually colonize the periurethral area and the vaginal introitus (Bollgren and Winberg 1976b). In addition, rectal colonization is often present during infection episodes. Bacteria that cause infections in otherwise healthy women express distinct virulence properties enabling them to establish an infection, whereas bacterial strains that cause infections in patients with complicating factors do not need to possess the same armamentarium of virulence factors (Dalet et al. 1991; Hull et al. 2002; Sandberg et al. 1988). Although the presence of special virulence factors is often accepted, this theory is not unchallenged. Selection of the infecting strain may just be a consequence of the heavy colonization by the pathogen. However, in recurrent asymptomatic bacteriuria the isolated strains appear to be a random sample of the fecal flora, whereas infecting strains do not appear to be such random samples (Lidin-Janson et al. 1977).

Adhesion

It is commonly accepted that the adherence of *E. coli* to uroepithelium is crucial to counteract the natural clearance of the urinary tract and to allow its colonization (Reid and Sobel 1987; Dalet et al. 1991; Tullus et al. 1991). Two classes of adhesins can be found on the surface of *E. coli*: fimbrial and nonfimbrial adhesins. While fimbrial adhesins carry ligands on their tips that bind to receptors present on cells, the structure and binding domains of nonfimbrial adhesins are less clear. Traditionally, *E. coli* adhesins are grouped according to the specificity of the hemagglutination they cause. Type 1 fimbriae, which are present on many Enterobacteriaceae, are inhibited by D-mannose and various mannosides. Hemagglutination by mannose-resistant fimbriae is not inhibited by D-mannose or mannosides and their receptors contain various carbohydrates.

The best studied of these are P fimbriae that bind to neutral globoseries glycolipids, including globote-

Table 1 *Percentage of bacterial species in urinary samples obtained in different clinical situations*

traosylceramide and trihexosylceramide, which are antigens of the P blood group system (Leffler and Svanborg-Eden 1981). The minimal receptor to which these fimbriae bind is α-D-Gal-(1→4)-β-D-Gal (Gal-Gal) (Bock et al. 1985; Källenius et al. 1981).

P fimbriae, like many other fimbriae, are synthesized from a polycistronic operon that codes for the structural proteins as well as for chaperone/usher proteins required for assembly of the final pilus. Figure 1 shows a model of the pilus structure. The pilus is anchored into the outer membrane by a protein that functions as an usher during pilus synthesis. The helical shaft is composed of the major structural subunit. The end of the pilus is fibrillar shaped and carries the adhesin (for detailed information see Mühldorfer et al. 2002; Saulino et al. 2000; Soto et al. 1998).

Donnenberg and Welch (1996)) used pooled data from many studies to show that P fimbriae are more often expressed by *E. coli* isolated from pyelonephritis (80.8 percent) than by strains from the fecal flora (relative risk of expression of P fimbriae in pyelonephritis, 6.1). In strains isolated from pyelonephritis complicated by bacteremia, the proportion of P frimbriated strains is even higher (88.9 percent). The prevalence of P-fimbriate *E. coli* in lower urinary tract infections is lower (31.1 percent), but these isolates still produce P fimbriae more often than fecal isolates (relative risk 1.98).

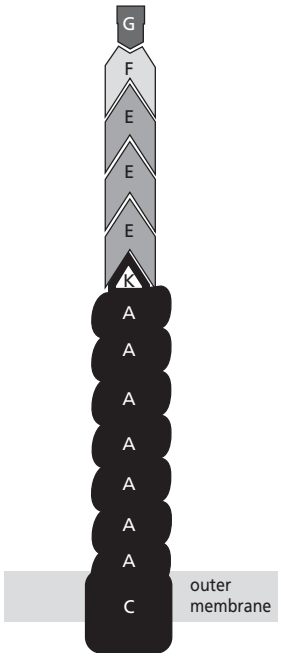

Figure 1 *General structure of* E. coli *fimbriae. The P pilus of* E. coli *consists of a helical shaft that is made up of PapA and a fibrillar structure projecting outwards that carries the adhesin, PapG, at its end. The diverse subunits are assembled by the major usher PapC that also anchors the pilus in the outer membrane. Between the shaft and the fibrillum and between the fibrillum and the adhesin there are adaptors, PapK and PapF. Synthesis of the shaft is terminated by PapH, which is buried in the channel formed by PapC (Soto et al. 1998). Assembly of type 1 pili is similar (Saulino et al. 2000).*

Immunuofluorescence with antibody to P fimbriae was used to show expression of these appendages by *E. coli* in vivo (Pere et al. 1987). In addition, patients with pyelonephritis caused by P-fimbriate *E. coli* mount an antibody response toward these antigens, pointing in the same direction.

Experimental evidence for the importance of P fimbriae comes from in vitro studies showing binding of fimbriated *E. coli* to tissue from human kidney, but not to the bladder epithelium (Donnenberg and Welch 1996) and from experimental infections using suspensions of P-fimbriate bacteria suspended in a solution of a receptor analogue, globotriosylceramide, to show reduced recovery of the infecting organism. In contrast, studies employing isogenic mutants did not always give unequivocal results. Mobley et al. (1993) constructed a mutant that lacked fimbrial components crucial to binding but could not show reduced pathogenicity in experimental infections of mice. Another group used a mutant that produced a truncated adhesin to infect monkeys. The parent and the mutant both established infections but the strain expressing P fimbriae persisted significantly longer (Winberg et al. 1995). These conflicting results may be explained by the presence of additional virulence factors in the strain used by Mobley's group.

Recently, Wullt et al. (2001) used a nonfimbriate clinical isolate and a transformant of the same strain expressing P fimbriae to infect volunteers. Bacteria expressing P fimbriae required lower inocula to reach significant densities within the urine and persisted longer than the wild-type strain. This experiment can be taken as a fulfillment of the molecular Koch's postulates (Falkow 1989) for P fimbriae.

The F1C fimbriae are one additional type of fimbria correlated with uropathogenicity. They interact with two minor glycosphingolipids, galactosylceramide and globotriaosylceramide, isolated from the rat, canine, and human urinary tract (Bäckhed et al. 2002). The authors also showed that binding of F1C-fimbriated *Escherichia coli* to renal cells induced interleukin-8 production, thus suggesting a role for F1C-mediated attachment in mucosal defense against bacterial infections. Strains producing F1C fimbriae are also more often isolated from patients with urinary tract infections than from fecal samples (22.3 percent in pyelonephritis, 13.9 percent in cystitis, and 6.2 percent in fecal samples). This indirect evidence of a role in pathogenesis is corroborated by an experimental infection showing that a mutant devoid of F1C fimbriae colonized the kidneys of rats in lower numbers than the mutant; however, reintroduction of a functional gene did not fully restore virulence (Marre et al. 1986).

Several other fimbrial and nonfimbrial adhesins (e.g. Dr, X, M, G) that confer mannose-resistant hemaggluti-

nation have been described in pathogenic *E. coli*. Association of these adhesins with disease or pathogenicity has not been shown conclusively although adhesins of the Dr series cause internalization of *E. coli* and thus may contribute to persistence of the organism (Goluszko et al. 1997).

Type I fimbriae cause mannose-sensitive hemagglutination. Although they are ubiquitious and can be found in many enterobacterial species and are present in most strains of *E. coli*, they are more often (odds ratio, 1.22) expressed by isolates from cystitis (64.1 percent) than by control isolates. In contrast, there is no such predilection in pyelonephritis (Donnenberg and Welch 1996). Type I fimbriae are known to undergo phase variation that is due to an invertible promoter (Eisenstein 1981; Abraham et al. 1985). Production of fimbriae is selected for by culture in liquid media as opposed to agar. When bacteria were grown under conditions favoring expression of type I fimbriae, the strains colonized the bladder of infected animals in higher numbers than phase variants not expressing fimbriae (Hultgren et al. 1985). Organisms colonizing the bladder were usually fimbriated while those recovered from the kidneys lost their pilation. When a mixture of mutants that expressed either phase constitutively was used to infect animals, the fimbriated strains were recovered in higher numbers than their nonfimbriated counterparts, especially during the early phase of the infection (Gunther et al. 2002). Type I fimbriae bind to uroplakins, major glycoproteins of the urothelial surface (Wu et al. 1996; Zhou et al. 2002). More recently, a study showed that *E. coli* expressing type I fimbriae persist longer and cause more severe symptoms than their nonfimbriated counterparts (Connell et al. 1996). These experiments included epidemiological data, as well as experimental infections. In addition, signature-tagged mutagenesis identified type I fimbriae amongst the most important virulence factors for urinary tract infections (Bahrani-Mougeot et al. 2002). In keeping with these results are observations that type I fimbriae mediate invasion of bladder epithelial cells by *E. coli* facilitating persistence and recurrent infections (Mulvey et al. 2000, 2001; Mulvey 2002). Once within the urothelial cell the bacteria may form intracellular biofilm-like pods in which they are embedded in a polysaccharide (Anderson et al. 2003). Accordingly, recurrent urinary tract infections in infancy seem to be caused by the same persisting strain (Jantunen et al. 2002).

In other uropathogenic bacteria, surface factors necessary for adherence have also been identified. *Proteus mirabilis* produces several fimbriae, some of which have a role in experimental urinary tract infections (Mobley 1996). For *Staphylococcus saprophyticus* a hemagglutinin that recognizes a protein receptor on the erythrocyte has been identified (Gatermann et al. 1992; Meyer et al. 1997). This adhesin has multiple functions as it is also the major autolysin of the species (Hell et al. 1998). It is also responsible for the attachment to uroepithelial cells (Meyer et al. 1996). Enterococci express an aggregation substance that contains an RGDS and an RGDV motif and thus binds to cells expressing appropriate integrins, which are receptors for these motifs (for a review see Gatermann 1996).

Hemolysin

It is a long standing observation that *E. coli* isolated from urinary tract infections more often show hemolysis on blood agar than strains from other infections. Analysis of pooled data from several epidemiological studies showed a higher prevalence of hemolysin-producing strains in pyelonephritis or cystitis than in feces. In addition, two studies used genetically manipulated strains to show that the hemolysin contributes to pathogenicity (Marre et al. 1986; O'Hanley et al. 1991). Recently, it was shown that expression of the hemolysin may contribute to renal failure (Kreft and Pagel 2000).

Cytotoxic necrotizing factor 1

A proportion of 40 percent of urinary isolates of *E. coli* produce this apoptosis-inducing cytotoxin (Caprioli et al. 1987). In experiments by Rippere-Lampe et al. (2001a, b), a isogenic mutant lacking expression of cytotoxic necrotizing factor 1 (CNF1) was less pathogenic in a mouse model than the parent strain. These findings were in contrast to experiments by Johnson et al. (2000). Thus, the function of this toxin remains controversial.

Iron siderophores

Iron is needed by almost all bacteria and free iron is present in exceedingly low concentrations in human serum and tissue. Aerobactin, a siderophore, is more often produced by *E. coli* causing infections, including urinary tract infections, than in fecal isolates (Carbonetti et al. 1986). Recently, Torres et al. (2001) showed that siderophores and TonB, a protein that facilitates transport of iron through the cytoplasmic membrane, are required in experimental infections.

Urease

As early as 1960 it was suggested that bacteria producing urease cause more severe urinary tract infections than urease negative bacteria (Braude and Siemienski 1960). Most studies used urease negative mutants generated by chemical mutagenesis or urease inhibitors to show a contribution of the enzyme to virulence (Griffith and Musher 1975; Griffith et al. 1976; Musher et al. 1975). In 1989, Mobley's group (Jones et al. 1990) as well as that of Gatermann (Gatermann and Marre 1989) used genetically manipulated strains of *Proteus mirabilis*

and *Staphylococcus saprophyticus*, respectively, to show that urease positive strains caused more severe damage to the urinary tract than their urease-negative derivatives. Urease is thought to act by increasing the urinary pH and the concentration of ammonium ions which may lead to precipitation of struvite ($MgNH_4PO_4$) or carbonate-apatite ($Ca_{10}(PO_4)_6 \cdot CO_3$) (Griffith et al. 1976; Johnson et al. 1993). In addition, urease may increase adhesion of bacteria to the urothelial cells (Parsons et al. 1984).

Organization of virulence factors

It has been shown in uropathogenic *E. coli* that virulence factors such as fimbriae and hemolysin are clustered in large segments of DNA, termed pathogenicity islands (Knapp et al. 1986). A pathogen may contain one or more of these islands and a crosstalk between genes encoded by the pathogenicity islands and chromosomal loci has been described (Morschhäuser et al. 1994).

THE PHYSIOLOGICAL FLORA OF THE URINARY TRACT

Normally, the bladder urine is sterile. In adults the distal urethra is colonized by a variety of microorganisms, including coagulase-negative staphylococci (excluding *S. saprophyticus*), viridans streptococci, diphtheroids, nonpathogenic *Neisseria* spp., anaerobic cocci, and lactobacilli. Commensal mycobacteria and mycoplasmas may also be present. In the postpartal period the flora consists predominantly of gram-negative bacilli, esp. *E. coli* (Bollgren and Winberg 1976a). Thereafter, in girls, the flora is replaced by anaerobic bacilli (Bollgren and Winberg 1976b; Bollgren et al. 1979).

Studies have shown that periurethral colonization is a prerequisite for the development of urinary tract infections (Bollgren and Winberg 1976b).

DIAGNOSIS

Sample collection

SUPRAPUBIC ASPIRATION

This technique is considered the diagnostic gold standard. Any species in any number is considered significant in urine obtained by suprapubic aspiration.

MIDSTREAM CLEAN-VOIDED SPECIMEN

As the distal urethra, the periurethral area, and the skin may be colonized by potentially pathogenic bacteria it is of paramount importance to avoid any contamination of the specimen by these bacteria. The most commonly used technique, the midstream urine, requires that the first 10–30 ml of the voided urine be discarded and the second, midstream portion be sampled. The first portion washes away nonadherent colonizing bacteria and the second portion mostly reflects the bacterial colonization of the bladder urine.

In the female patient, adequate periurethral cleansing is necessary to reduce the probability of contamination. For cleaning, water or a soap solution without antibacterial activity should be used as residues of antibacterial soap or disinfectants may impair culture results.

In men, the foreskin should be retracted and the external meatus should be cleansed. There has been some debate whether cleansing is really necessary (Lipsky et al. 1984); however, as it is easily done and decreases the number of contaminated specimens, some authorities recommend this procedure (Schaeffer 1994).

STRAIGHT CATHETERIZATION

Although this procedure yields specimens of a quality similar to that of suprapubic aspiration, it bears the risk of introduction of bacteria into the bladder and bacteriuria after straight catheterization is not uncommon (Eisenstadt and Washington 1996). The technique may be considered if correct clean-voided specimens cannot be obtained and suprapubic aspiration is contraindicated or not feasible.

Specimen transport

Urine should be cultured within 2–4 h. If longer delays cannot be avoided the specimen should be refrigerated to preserve the bacterial density. Transport devices containing boric acid as a preservative have been developed to allow unrefrigerated transport of specimes. However, culture results after prolonged storage of specimens may be altered significantly (Gillespie et al. 1999).

Culture

Bacteriuria is defined as the presence of bacteria within the urinary tract. The central problem in interpreting bacteriuria by the examination of voided urine is to distinguish between contamination originating from the physiological flora and bacteriuria that originates in the normally sterile parts of the urinary tract. Kass (1957) observed that some healthy women have bacteriuria, but the number of colony-forming units (cfu) in their urine was considerably lower than that in urine collected from women with pyelonephritis. In pyelonephritis the urine of 95 percent of patients contained $>10^5$ bacteria per ml, whereas this density was only rarely reached in asymptomatic women (6 percent). The number of 100 000 organisms per ml in a carefully collected sample of clean-voided or midstream urine has since then become the threshold for ‘significant’ bacteriuria.

Later studies have shown, however, that this threshold may not be applicable to cases of uncomplicated cystitis (Stamm 1988), or posterior urethritis (Stamm et al. 1980; Latham et al. 1985). In these infections colony counts as low as 10^2/ml have been found. Therefore colony counts of $<10^5$/ml may be significant when the clinical diagnosis of uncomplicated cystitis has been established, in cases of complicated urinary tract infections colony counts are usually $>10^5$/ml (Naber et al. 2002). However, cases of uncomplicated cystitis are usually treated empirically, without taking urinary cultures (Warren et al. 1999; Le and Miller 2001).

Consequently, many guidelines for microbiological diagnostic workup of clean-voided urine require a species (or isolate) specific enumeration to distinguish contamination from colonization (Clarridge et al. 1987; Gatermann et al. 1997; Kouri et al. 2000; Naber et al. 2002). The diagnostic interpretation is made relative to the clinical diagnosis or situation. In complicated urinary tract infections the number of 10^5 colony-forming units per ml is considered significant, whereas in clearly uncomplicated cases the threshold is 10^2. Specimens from indwelling catheters may present a special situation since colonization with multiple organisms even in high densities is common (Warren et al. 1982).

The diagnosis of urinary tract infections thus requires a method that is capable of simultaneously determining the colony-forming units of all viable bacterial species present in the sample. Traditionally, this has been done by the pour plate method, where a sample of the urine is mixed with a fixed volume of nutritient agar and plates are poured. The number of bacteria per volume can be determined by multiplying the number of colonies with the dilution factor of the urine. Although this method is most precise, it is also cumbersome and time-consuming. Many laboratories, therefore, use the surface streak technique where a calibrated loop is dipped into the urine and the volume held by the loop is applied to the surface of the appropriate agar media. Commercial single-use loops hold 1 or 10 µl of urine, thus the number of cfu per ml is calculated after incubation by multiplying the number of colonies by 1 000 if a 1-µl loop was used or by 100 if a 10-µl loop was used. There is some evidence that 1-µl loops lack precision and underestimate the true number of bacteria in the sample (Frimodt-Møller and Espersen 2001). Most often, media that permit growth of gram-positive bacteria, including β-hemolytic streptococci, e.g. sheep blood agar, and selective media for Enterobacteriaceae, e.g. MacConkey agar, are inoculated. Cystine lactose electrolyte-deficient agar may also be used, although some gram-positive species grow less well than on blood agar.

Simple, semiquantitative culture methods, such as the filter paper method (Kunin and Buesching 2000) and dipslide cultures have also been developed. These techniques are useful as screening techniques but lack sensitivity for fastidious organisms (Eisenstadt and Washington 1996). In addition, technical problems, such as the detachment of the agar from the paddle or dried out agar in dipslide cultures, can occur.

Due to the limited spectrum of bacteria that cause urinary tract infections identification of causative species can usually be done with a reduced set of tests (Baron 2001). However, care must be exercised not to overlook the unusual or rarely encountered species (Damron et al. 1986). Corynebacteria and some gram-positive cocci may require prolonged incubation and other species such as *Haemophilius* or *Gardnerella* or even a fastidious enterobacterial strain may not grow on the routinely used media. It is therefore advisable to be suspicious, especially in cases where UTI is clinically suspected, pyuria is present, but routine cultures are negative. In such cases an infection with mycobacteria, mycoplasmas, or chlamydia should be ruled out and the unusual should be sought.

Some authors recommend testing of urine samples for the presence of antimicrobial substances (Ansorg et al. 1975; Abu Shaqra 2001) which may mask the presence of bacteria in the urine. To this end, a small volume of urine is placed on an agar plate inoculated with an indicator bacterium (e.g. *Bacillus subtilis* or *Staphylococcus aureus*) and any inhibition of bacterial growth is taken as evidence for the presence of antibacterial substances.

Extrapulmonary tuberculosis may affect the kidneys, prostate, epidymis, or testes. Mycobacterial infections of the kidneys often present with pyuria, but fast-growing bacteria cannot be isolated from the urine. Clinical symptoms suggestive of cystitis may be present and the intravenous pyelogram is usually abnormal (El Khader et al. 1997). Diagnosis is based on cultural detection of *Mycobacterium tuberculosis* in urine, if renal tuberculosis or in ejaculate, if epididymitis is suspected.

Infections with mycoplasmas and chlamydia usually affect the urethra but symptoms may suggest cystitis. As expected, bacterial densities are highest in the first portion of a voided urine and suprapubic aspiration is usually negative. Sensitive and specific tests, molecular genetic amplication techniques, have been described that detect chlamydia in genital specimens (Van Der Pol et al. 2001; Vincelette et al. 1999). Mycoplasmas may be grown from urethral samples although a swab offers higher sensitivities than urine cultures. In addition, *M. hominis* is part of the normal flora of the urethra.

In many countries, standardized protocols for the culture and interpretation of urine samples have been developed (Clarridge et al. 1987; Gatermann et al. 1997; Kouri et al. 2000).

Deprecated procedures and unacceptable specimens

Midstream urine or urine obtained via a catheter should not be cultured anaerobically and should not be

inoculated into enrichment broths. Urine should not be centrifuged to culture the sediment.

Foley catheter tips, urine inoculated into broth media, urine sediment, native urine that has been stored unrefrigerated for more than 2 h, or dried dip slides are unacceptable for culture.

Interpretation of urine cultures

For a meaningful interpretation of culture results the clinical situation (complicated, uncomplicated UTI, asymptomatic patient), the patient's sex and the type of the specimen (clean-voided, catheter, suprapubic aspiration) must be available. Also, the number of different bacterial species and their respective number of colony-forming units must be known. Interpretation guidelines aggregate these pieces of information into reasonable laboratory interpretations of culture results and give suggestions for further diagnostic workup, e.g. identification and susceptibility testing. Generally, these guidelines consider pure cultures of typical urinary pathogens to be significant if present in $\geqslant 10^4$ cfu per ml. In acute, uncomplicated cystitis the thresholds are lower, e.g. 10^3 per ml, whereas in complicated infections they may be higher (10^5 per ml) (Clarridge et al. 1987; Gatermann et al. 1997; Kouri et al. 2000; Naber et al. 2002). Repeated isolation of the same microorganism increases the specificity of the result and is absolutely necessary if asymptomatic bacteriuria is to be detected (Pattaragarn and Alon 2003).

In patients with chronic indwelling catheters, cultures often yield more than one potential pathogen regardless of patients' symptoms (Warren et al. 1982). These specimens therefore reflect colonization rather than infection. It is rarely necessary to perform urinary cultures in asymptomatic patients with indwelling catheters because high colony counts may reflect infection or colonization and low bacterial densities usually increase to high ($>10^5$) levels within a few days (Stark and Maki 1984). In symptomatic patients with flank pain or fever, a diagnostic workup of all organisms may be indicated (Gatermann et al. 1997).

Candida spp. is often isolated from the urine of catheterized patients who receive antibiotic treatment and antibiotic therapy is the most important risk factor for candiduria (Lundstrom and Sobel 2001; Weinberger et al. 2003). However, since candiduria may also be a symptom of deep-seated candidal infection, patients should be carefully evaluated to exclude such condition (Fisher et al. 1995).

MANAGEMENT OF URINARY TRACT INFECTIONS

A plethora of literature exists concering the treatment of urinary tract infections. Most current guidelines recommend either trimethoprim/sulfmethoxazol or a fluoroquinolone for empiric therapy of uncomplicated cystitis. These antibiotics are usually given for 3 days. β-lactam antibiotics are less satisfactory, because recurrences are more frequent (Johnson and Stamm 1989) and longer therapies may be needed. During pregnancy trimethoprim/sulfmethoxazol or quinolones cannot be used and a susceptible β-lactam antibiotic is the therapy of choice (Naber et al. 2002). In uncomplicated cystitis in nonpregnant women, the narrow bacterial spectrum permits empiric therapy without the aid of a urine culture. In pregnant women a urine culture may be needed to select the most appropriate agent (Naber et al. 2002).

In patients with acute uncomplicated pyelonephritis, oral therapy can be an alternative to the classical intravenous regimens (Warren et al. 1999; Naber et al. 2002). As with uncomplicated cystitis, a fluoroquinolone, or, if susceptibility has been established or is likely, trimethoprim/sulfmethoxazole is usually appropriate. However, a urine culture should be obtained to guide therapy in poorly responding individuals.

Although most standards recommend the use of trimethoprim/sulfamethoxazole or fluoroquinolones as a first-line treatment (Johnson and Stamm 1989; Warren et al. 1999), the most appropriate therapy is contingent on the local situation, because susceptibility towards antimicrobials may vary widely between geographic regions. For trimethoprim/sulfamethoxazole resistance rates for *E. coli* as high as 45 percent have been described in some regions (Mazzulli 2002; Farrell et al. 2003; Gales et al. 2003) and it has been recommended that fluoroquinolones be used if resistance rates to trimethoprim/sulfamethoxazole exceed 20 percent (Le and Miller 2001). However, resistance to fluoroquinolones is also emerging and resistance rates of 10 percent in *E. coli* are common (Mazzulli 2002; Farrell et al. 2003), and up to 20 percent have been described (Gales et al. 2003).

In complicated urinary tract infections treatment should be based on the results of a urinary culture, because the spectrum of causative organisms is much larger and resistance to antimicrobial agents is frequent (Naber et al. 2002).

Asymptomatic bacteriuria should be sought for and treated in pregnant women (Smaill 2002), because it is a risk factor for pyelonephritis, low birth weight, and early delivery. In contrast, screening for and treatment of asymptomatic bacteriuria in diabetic women (Harding et al. 2002) and patients with renal transplants is probably not indicated (Muñoz 2001).

Prophylaxis

Given the fact that most patients experience only one UTI in their lifetimes, prophylactic measures are needed only for women suffering frequent recurrences. If it has

been established in an individual that episodes of acute UTI frequently occur after sexual intercourse, a prophylactic dose of an antibiotic may be (Stapleton and Stamm 1997) indicated. In some women, for periods of clustering of UTIs a regular dose of an antibiotic may suppress infections. Currently there is no evidence that cranberry juice reduces the frequency of urinary tract infections (Jepson et al. 2002).

There have been many attempts at developing vaccines against UTI with *E. coli* and *P. mirabilis*. Whole cell killed vaccines or vaccines based on single virulence factors have been used in animal models to show that the animals were protected against challanges with strains expressing the respective virulence factor (Langermann et al. 2000; Li and Mobley 2002; Uehling et al. 1994a, b, 1997). Since many different virulence factors contribute to pathogenicity it is unlikely that one single factor will be sufficient to offer protection.

INTRODUCTION

Bone and joint infections pose a number of challenges to the academic and the clinical microbiologist. From the academic standpoint the pathogenesis of musculoskeletal infection, and the pathophysiology of the osteomyelitic lesion or the infected prosthetic joint, remain incompletely understood (Mandal et al. 2002). So too do the molecular mechanisms of infection-related bone destruction (Josefsson and Tarkowski 1999; Nair et al. 2000; Tarkowski et al. 2002) or bacterial persistence in the face of host defenses and antibiotic use.

From the clinical microbiology perspective, there can be significant difficulties to be overcome in the interpretation of microbial cultures, notably because of the role of skin commensals in device-related infection. Additional problems are generated by those clinical scenarios where bone, infected as a consequence of soft tissue loss, is then sampled through the resulting soft tissue defect.

Having isolated bacteria and formed a view about their relevance, the clinical microbiologist is frequently challenged when feeding that information into a management plan. This is partly because of a relative lack of a strong evidence base for recommendations about durations of treatment or the mode of delivery of antimicrobials. It is also because of the strongly surgical nature of the specialty. The microbiologist must exercise skills in multidisciplinary working and to be credible, must demonstrate an understanding not only of his own field, but also of the major orthopedic imperatives and drivers.

Given the very significant morbidity caused by bone and joint infection, and the substantial health gains for patients who are treated successfully, there are major benefits for patients and clinicians (of all disciplines) when the clinical microbiologist can participate in, and if need be lead, effective multidisciplinary working for the management of these problems (Ziran et al. 2003).

CLINICAL MANIFESTATIONS

Musculoskeletal infection, affecting bone and joint, may be acute or chronic. Any part of the skeleton may be affected, and bacteria may reach the tissues of the skeleton through hematogenous or contiguous spread. The range of manifestations most commonly seen is outlined in Table 1.

EPIDEMIOLOGY

The epidemiology of musculoskeletal infection is a reflection of the prevalence, in the population, of underlying risk factors for bacteremia, trauma, and instrumentation on the one hand, and the geographical distribution of pathogens on the other.

In industrialized societies, in which antibiotics are relatively available, child health is good, and orthopedic

Table 1 *Commonly seen range of manifestations*

Manifestation	Site of infection	Presentation	Soft tissue component	Causative pathogen(s)
Septic arthritis	Native	Acute	–	MSSA, BHS, HIB, GC
	Prosthetic		+	MRSA, MSSA, CoNS GNR
	Native	Chronic	–	MTB, Lyme, MSSA
	Prosthetic		++	CoNS, SA, BHS, EC, GNR
Osteomyelitis	Hematogenous	Acute	–	MSSA, BHS, HIB, *Salmonella*
	Contiguous focus		+	MSSA, MRSA, GNR
	Hematogenous	Chronic	++	MSSA, BHS, GNR
	Contiguous focus		+++	MSSA, MRSA, CoNS, BHS, GNR, EC
Vertebral osteomyelitis and discitis	Hematogenous	Chronic	–	MSSA, GNR, MRSA
	Contiguous focus (post surgical)	Acute	–	MRSA, MSSA, CoNS
Fracture-fixation infection	Contiguous focus	Acute	–/+	MSSA, MRSA, GNR
		Chronic	++	MSSA, MRSA, CoNS, GNR
Osteomyelitis 2° to pressure sore including diabetic foot ulcer		Chronic	+++	MSSA, MRSA, CoNS, BHS, GNR, AnO2, EC

ANO2, anaerobic rods; BHS, β-hemolytic streptococci; CONS, coagulase-negative staphylococci; EC, *E. coli*; GC, gonococci; GNR, gram-negative rods; HiB, *H. influenzae* type b; Lyme, Lyme borreliosis; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-susceptible *S. aureus*; MTB, *Mycobacterium tuberculosis*; SA, *S. aureus*.

management includes energetic trauma management and joint replacement, there has been a decline in 'classical' presentations. Advances in fracture management mean that infections of fracture fixations have replaced infections of open fractures (Gustilo and Anderson 1976); childhood hematogenous bone and joint infection is in decline and more frequently presents in a subacute manner (Gonzalez-Lopez et al. 2001; Blyth et al. 2001; Rasool 2001); hematogenous infections of the spine in the elderly are increasing in incidence (Jensen et al. 1997; Chelsom and Solberg 1998; Krogsgaard et al. 1998), as is osteomyelitis secondary to pressure sores (Sugarman 1987). Infections of prosthetic joints are now the most formidable manifestation of septic arthritis (Malchau et al. 1993), a role occupied by tuberculosis some 50 years ago, and by *Staphylococcus aureus* in the pre-antibiotic era.

Much of this remains a contrast to less developed areas of the world, where higher incidences of soft tissue infection, and less universal access to healthcare, perhaps explain the higher recorded incidences of conditions such as acute septic arthritis and osteomyelitis (Gillespie 1990). Limited healthcare resources may restrict access to joint replacement or complex orthopedic instrumentation, but correspondingly make all the more serious the impact of infection on traumatic wounds. Combat and landmine injuries from military conflict are important in this regard, as are injuries from increasing numbers of industrial and road traffic accidents, though systematic data on this are hard to find. As a result, chronic osteomyelitis remains a considerable problem (Museru and Mcharo 2001).

Certain manifestations appear to have a truly worldwide importance. The global epidemic of Type 2 (non-insulin dependent) diabetes is responsible for a dramatic increase in problems due to neuropathic foot ulceration, including osteomyelitis (Lipsky et al. 1990). Because patients with this disease survive for relatively long periods without expensive treatments, developing countries share with the industrialized nations a rising prevalence of diabetics with neuropathy and secondary foot ulceration, frequently leading to osteomyelitis (Abbas et al. 2002).

From a microbiological perspective, although certain pathogens such as *Staphylococcus aureus* are universally important, others are restricted by geographical or occasionally socioeconomic factors. These include the predominant distribution of methicillin-resistant *Staphylococcus aureus* (MRSA) within that group of society in frequent contact with healthcare institutions and nursing homes (Blanc et al. 2002); and the greater prevalence of infections due to *Mycobacterium tuberculosis*, *Mycobacterium leprae*, and *Brucellosis* spp. in tropical countries (McGill 2003).

Table 2 summarizes available epidemiological data on incidences, prevalence, and risk factors of the various manifestations of musculoskeletal infection.

PATHOGENESIS

The pathogenesis of bone and joint infection, as understood to date, is a multistep process (Mandal et al. 2002). Organisms gain access to musculoskeletal structures and proliferate. This may occur in both planktonic

Table 2 *Epidemiology of musculoskeletal infection*

Manifestation	Incidence	Prevalence	Risk factors
Acute septic arthritis	10–100/100 000/yr	N/A	In Australasia, indigenous race (Gillespie 1990)
Chronic septic arthritis	N/A	Unknown	Delayed diagnosis or inadequate treatment of acute septic arthritis
Acute prosthetic joint infection	1–2% of joint replacements	N/A	Prior joint surgery; adverse wound score, ASA status or prolonged surgery; history of cancer; superficial wound infection (Berbari et al. 1998a)
Chronic prosthetic joint infection	N/A	Unknown	As for acute infection
Acute osteomyelitis		N/A	None proven. Soft tissue infection and bacteremia presumed
Chronic osteomyelitis: hematogenous	N/A	Unknown	Delayed diagnosis or inadequate treatment of acute osteomyelitis
Acute fracture fixation infection	Unknown percentage of high energy tibial fractures without free flap soft tissue cover	N/A	Open fracture; high energy injury; Inadequate debridement; failure to establish early soft tissue cover (Gustilo and Anderson 1976)
Chronic fracture fixation infection	N/A	Unknown	Inadequate management or delayed diagnosis of acute fracture fixation infection
Chronic osteomyelitis due to diabetic foot ulceration	Unknown	Unknown; 4–10% of diabetics have ulcers; 10–40% of ulcers have osteomyelitis	Increasing size, depth and chronicity of ulcer; failure to heal despite correction of ischemia and adequate offloading
Chronic osteomyelitis: other pressure sores	Unknown		Increasing size, depth, and chronicity
Vertebral osteomyelitis		Unknown	Increased age; intravascular catheterization; intravenous drug use

N/A, not applicable.

and sessile states. In each situation, intercellular signaling within the bacterial population orchestrates the expression of genes involved in host tissue damage (Abdelnour et al. 1993) and in the formation of biofilms (Chopp et al. 2003; Kjelleberg and Molin 2002), believed relevant to persistence of infection. Host inflammatory responses have both protective components (in terms of the prevention of septicemia and the long-term preservation of function) and harmful ones (joint damage and bone death) (Josefsson and Tarkowski 1999). Reparative and resorptive responses are seen in bone, the mechanisms of which are beginning to be elucidated.

Access of organisms to bone or joint

Microorganisms can gain access to bone, joint or muscle via hematogenous spread or from a contiguous source of infection or contamination.

Direct inoculation of pathogens via the latter mechanisms, though apparently self-evident, needs a little more consideration. It is noteworthy that it appears to be relatively difficult to infect healthy bone. In many experimental models, it is necessary to injure bone in some way (Norden 1988; Rissing 1990); one of the classic models involves injecting the sclerosing agent sodium morrhuate into the bone marrow prior to a bacterial challenge. Other models have involved surgically creating a cavity, a devitalized segment of a long bone, or a fracture (which can then be plated or pinned), or even resecting a joint and inserting foreign material to mimic joint replacement (Mader 1985; Belmatoug et al. 1996; Smeltzer et al. 1997b; Kaarsemaker et al. 1997; Monzon et al. 2002). In the majority of cases the pathogens are then directly inoculated, though hematogenous challenge can also be employed (Bremell et al. 1991).

These observations appear to find a direct parallel in human disease, in which the majority of contiguous source infections are in contexts where bone is indeed injured. This includes both elective orthopedic and emergency trauma surgery, and infections related to chronic soft tissue defects. Elective surgery usually involves cutting, drilling or instrumenting bone to achieve the desired end, whether that be joint replacement, realignment of the axis of a long bone, fusion of one or more joints, or the removal of a painful bony pressure point or joint. In trauma, fractures may involve one or more bones with variable severity depending on the energy of the injury, and may extend into the joint line, forming a potential route for the spread

of infection. Bone may be directly devitalized by dissipation of the high fracture energies through it, and acutely devascularized by stripping of the soft tissue attachments normally providing the periosteal circulation. This vascular compromise may be compounded by intramedullary nailing (affecting the endosteal circulation) or by further soft tissue stripping performed to gain access to the fracture for its reduction.

Soft tissue loss is also the key initiating element in the pathogenesis of osteomyelitis secondary to decubitus and diabetic foot ulceration. In the former case, immobility, poor prior skin condition, incontinence, and reductions in sensation, all play roles in allowing excess chronic pressure to develop and lead to ischemic soft tissue necrosis. In the case of the diabetic foot, peripheral neuropathy is the key driver (Boulton 1996). Motor neuropathy causes an imbalance of intrinsic and extrinsic musculature, leading to a high arched foot with subluxation at the metatarsophalangeal joints and clawing of the toes. There are also alterations in the compliance of skin and deeper tissues as a result of long-term hyperglycemia and autonomic neuropathy. These changes in the biomechanics of the foot cause excessive pressure on metatarsal heads, heel, tips of clawed toes, and dorsal aspects of interphalangeal joints (on the inner upper surface of footwear) (Murray et al. 1996). Sensory neuropathy causes a lack of protective sensation (without necessarily total numbness) and repetitive loading of the new pressure points leads to ulceration.

Once ulceration develops, it may worsen either through continuing loading, or infection, or both. Once the tissues directly overlying and attaching to bone become involved, the periosteal circulation is compromised and the most superficial cortical layer of bone is at risk. The high numbers of bacteria located in the ulcer base are then situated directly adjacent to injured bone for the initiation of infection.

It is also relevant, in considering infections relating to direct inoculation, to recall the important potentiating role played by devitalized tissue or foreign inanimate matter if present. Since the elegant experiments of Elek and Conen (1957) it has been clear that foreign materials greatly lower the inoculum required to initiate infection, and increase its severity. In elective orthopedic surgery, the use of metal ware and bone cement provides extensive surfaces for colonization with microbes if a breach in sterile technique occurs. In trauma and its management, bony injury also includes variable soft tissue loss and damage, and environmental contamination with dirt, soil, vegetable matter or debris from road surfaces or projectiles. All these factors potentiate infection just as in animal models. They also provide an explanation for the microbiology of this group of conditions, since pathogens are derived from the contaminating external environment or from the skin, and include low-virulence organisms when metal ware is involved (Christensen et al. 1994).

Hematogenous spread is clearly of importance in a number of manifestations. A range of bacteria can, under certain conditions, translocate into a joint space, or set up a focus of infection within bone, usually at the metaphysis just proximal to the growth plate. Although the in vivo mechanisms of this are poorly understood, *Staphylococcus aureus* does display the ability to adhere to and invade cultured human endothelial cells in vitro (Peacock et al. 1999). This is mediated by interactions between the staphylococcal cell wall-anchored fibronectin-binding protein and cell surface-associated fibronectin (Peacock et al. 1999), an interaction involving specific modules within each of these macromolecules (Massey et al. 2001a). Internalization is dependent upon endothelial cell membrane integrins ($\alpha5\beta1$), which appear to generate signals that drive active bacterial uptake on engagement of the fibronectin (Fowler et al. 2000; Massey et al. 2001a). Once within the endothelial cell, bacteria can escape into the cytosol (Bayles et al. 1998), and can persist for prolonged periods of time (several days at least) (Ellington et al. 2003).

The fate of endothelial cells following bacterial uptake varies according to toxin elaboration by the bacteria. If α-toxin is produced, endothelial cell death follows rapidly (Buerke et al. 2002). If cells do not die, they upregulate adhesion molecules and become pro-adhesive for white cells (Beekhuizen et al. 1997). In vivo, this would lead to adhesion of white cells, platelets and the formation of microthrombus; significantly, *Staphylococcus aureus* also has receptors for components of thrombus such as fibrinogen and thrombospondin. If there is no toxin production, persistence or translocation are possible outcomes.

Adhesion is considered to be the next crucial step once bacteria have reached bone or joint (Gristina et al. 1985), the importance of which appears to be borne out by the possession, in the case of *Staphylococcus aureus*, of numerous cell wall-associated molecules that act as proteinaceous receptors for a range of cell matrix or cell-surface associated proteins (Smeltzer et al. 1997a). These include receptors for collagen, fibronectin, bone matrix sialoprotein, and osteopontin (Herrmann et al. 1988; Buxton et al. 1990; Park et al. 1991, 1996; Patti et al. 1992; Switalski et al. 1993; Yacoub et al. 1994). As with direct inoculation of bacteria onto wounded bone, there is a plausible relationship between these adhesive properties and the observation that a proportion of cases of hematogenous infection of bone occur following blunt trauma. In healthy bone the components of the osteoid matrix are not exposed, being covered in mineral, but on injury, the underlying matrix becomes accessible to external agents including bacteria. For *Staphylococcus aureus*, some data support the importance of the collagen binding protein, Cna, in the pathogenesis of bone and joint infection (Patti et al. 1994; Elasri et al. 2002), though other carefully conducted studies of clinical isolates have not confirmed that this specific protein

is either necessary or sufficient (Thomas et al. 1999). The gene *cna*, encoding the collagen binding protein, may however be a more general marker of virulence. It was identified, along with the fibronectin binding protein gene *fnb*, as one of seven genes that appeared to be independently and cumulatively associated with the potential to cause invasive staphylococcal disease (Peacock et al. 2002); in the study concerned, some of the cases certainly had bone and joint manifestations of infection. It is possible that microfracture following blunt trauma produces areas of microscopic thrombus, or exposed bone matrix proteins, that provide a site for bacterial adhesion via Cna or Fnbp.

Adhesion is also of importance when considering infection of orthopedic metal ware of any kind. It has been shown that foreign materials are rapidly 'conditioned', after insertion into the body, by the deposition of plasma proteins such as fibronectin (Delmi et al. 1994). These proteins provide an ideal substrate for bacterial adhesion, though some important device-related pathogens, such as coagulase-negative staphylococci, have relatively weak adhesion mechanisms for fibronectin. They are, however, able to adhere relatively well to unconditioned metal and plastic, via a number of macromolecules, and subsequently establish very strong associations through the production of biofilm (see below) (Christensen et al. 1994).

Quorum sensing

A well-recognized clinical pattern in bone and joint infection is a prodromal illness that may include features suggestive of transient bacteremia, resolving completely, and then followed by acute infection of bone or joint. In such cases there is a high prevalence of bacteremia at the time of presentation, but without clinical evidence to suggest that this has persisted since the initial seeding of the joint. This is compatible with current understanding of the importance of quorum sensing, and global regulation of gene expression, in many pathogens. In *Staphylococcus aureus*, a cyclic octapeptide that is the product of the *agr* locus acts as a density-dependent signal to the whole bacterial population (Ji et al. 1995), ultimately resulting in the transcription of a regulatory RNA molecule, RNA III (Novick et al. 1993). This affects the expression of a wide variety of genes, many responsible for adhesin or toxin production (Novick 2003). Expressed during logarithmic phase, and triggering RNA III expression as the population moves towards stationary phase, *agr* upregulates toxin production and downregulates adhesin expression. Teleologically, as their growth rate slows through nutrient depletion, organisms become less adhesive and more destructive to surrounding cells and tissues, and so more able to disseminate to new sites. This fits with the observed sequence of a clinically unapparent bacteremia that leads to the onset of symptoms within a joint, followed by a secondary bacteremia detected at presentation. The *agr* gene is present in coagulase-negative staphylococci (Van Wamel et al. 1998) where it may be able to interfere with the *agr* expression of *Staphylococcus aureus* (Tegmark et al. 1998). It has been speculated that in this way, coagulase-negative staphylococci could act as negative regulators of the natural virulence of *Staphylococcus aureus*.

Biofilm formation and other mechanisms of persistence

Quorum sensing is also likely to be important within biofilms and during biofilm formation (Davies et al. 1998; Vuong et al. 2003). A biofilm is an adherent consortium of microorganisms embedded in an exocellular polysaccharide (glycocalyx) (Costerton et al. 1999; Gotz 2002). This material protects bacteria from complement and from phagocytes and, within the biofilm, organisms are present that are able to act as 'persisters', with growth states that confer relative resistance to antibiotics and other microbicides. The initial events in the formation of these structures occurs surprisingly rapidly; in *Pseudomonas aeruginosa*, studies have demonstrated how immediately after adhesion to a substrate, bacterial cells begin to express genes involved in alginate synthesis. The genetics of this process are well understood for *Pseudomonas aeruginosa*, and are increasingly so for *Staphylococcus epidermidis* (Heilmann et al. 1996), in which the *ica* gene cluster orchestrates the production of biofilms (reviewed in Gotz 2002). The *ica* operon is also represented in *Staphylococcus aureus*, and is another of the seven virulence factors previously mentioned that are associated with invasive characteristics (Peacock et al. 2002).

Other mechanisms of bacterial persistence have been suggested as potentially relevant. The clinical picture of osteomyelitis includes chronic active sepsis, but also periods of relative or complete remission, with subsequent relapse. Recurrent infection can occur many years after the initial episode, prompting speculation as to the mechanism of such long-term survival. One hypothesis is that small colony variants (SCV), which under certain conditions have been shown to emerge rapidly in populations of staphylococci, might survive for prolonged periods inside long lived cells such as fibroblasts. Certainly SCVs can be demonstrated as a surviving intracellular bacterial population in cultures of endothelial cells when host cell death is prevented through external antibiotic use. *Staphylococcus aureus* can invade a wide range of host cells including fibroblasts, and SCVs are known to have high rates not only of induction, but also of reversion to wild type characteristics. Furthermore, SCVs have been shown capable of causing osteoarticular infection in vivo in animal models

(Jonsson et al. 2003). Finally, a careful study has shown that SCVs can be isolated, in some cases in almost pure growth, from individual cases of relapsed chronic osteomyelitis (Proctor et al. 1995). The general relevance of this observation remains to be demonstrated, but it is an appealing hypothesis that SCVs, located within cells or indeed deep within a biofilm, provide a mechanism for remission and relapse. They may even, through rapid switching to and from wild type, allow populations of bacteria to manifest antibiotic resistance (a feature of SCVs) (Chuard et al. 1997) without the fitness costs usually associated with true antibiotic resistance (Massey et al. 2001b).

Inflammatory responses

BONE RESPONSES

Acute infection in bone and joint leads to acute inflammation. An influx of neutrophils, accompanied by increased vascular permeability and edema, is seen both in infected synovium and in cancellous bone. These responses are important in protection of the host against the secondary bacteremia commonly seen in acute infections, but they also contribute to the immediate damage to the infected part of the skeleton (Josefsson and Tarkowski 1999). The inflammatory response within the joint leads to an outpouring of synovial fluid and a tense effusion. In joints such as the hip and shoulder, where the head of the femur and humerus, respectively, are supplied with blood via recurrent vessels running up the neck of the bone, the high intra-articular pressure may be enough to compromise the circulation in those vessels. Within cancellous bone at any site, edema also leads to high pressures and potential vascular compromise. The procoagulant effects of inflammatory cytokines on vascular endothelium exacerbate this. The consequence is that the inflammatory response frequently leads to areas of bone death, through microvascular thrombosis around the infected focus. If the area of infection is not contained, progressive bone death can result.

The tracking of infection through areas of cancellous or cortical bone leads to other key features of bone infection. Infection originating in the metaphysis of a long bone, the common site for hematogenous infection, can track via the Haversian canals through the cortex and into the soft tissue. Where the periosteum is loosely connected, the accumulation of pus results in a subperiosteal abscess, stripping off the periosteum from the bone. As with traumatic periosteal stripping, this results in further vascular compromise to the bone, already affected internally by the inflammatory focus. A whole segment of bone death can result from the combination of endosteal infection and a circumferentially developing sub-periosteal abscess.

Bone is a highly dynamic structure adapted to respond to biomechanical forces and to preserve function. The response to periosteal stripping is to form new bone beneath the elevated tissue. In a fracture, this would be the beginning of fracture callus, which would then involve the fracture hematoma and so lead to healing. In infection, the periosteal reaction leads ultimately to the formation of new bone that externally bridges the involved segment. Where an area of dead bone would compromise the mechanics of the bone, this is therefore compensated for by the production of the new bony involucrum. Although this may mean that there is dead bone (now relatively trapped within the new bony shell), it does also mean that function, the basic role of the skeleton, is preserved.

Developing in parallel with the process of new bone formation is bony resorption in the areas contiguous with the dead bone. This is a direct consequence of the inflammatory response. There is evidence that inflammation both enhances the activity of professional bone resorbing cells (osteoclasts) and triggers bone resorption by 'semi-professional' cells such as recruited polymorphs. Bone resorption in the area of infection and inflammation acts to separate the dead bone from living bone. The resulting fragment(s) of dead bone, called a sequestrum, lying within the living bone, may now act as a site for permanent infection from a resident population of adherent bacteria, but this phenomenon also opens up the possibility of self-cure. If the sequestrum can be fragmented or is of sufficiently small size (since not all infections cause large areas of bone death), it can potentially be extruded, leaving behind living bone capable of healing. Spontaneous extrusion of sequestra is seen to occur in both chronic hematogenous and contiguous focus osteomyelitis. Bone is discharged either through the soft tissue defect that caused the infection, or through sinus tracts, the formation of which is another characteristic of chronic osteomyelitis. Sinuses occur because of the destructive nature of pus under pressure, which will track along tissue planes (e.g. beneath the periosteum), but will frequently then breach fascial barriers and eventually find a route to the outside world.

Bone resorption is also of key importance in the pathogenesis of bone infections related to orthopedic metal ware. Here, the impact of the infection is not merely how it affects the host systemically and through local damage. It is also that bone resorption, occurring adjacent to the infected orthopedic device, results in mechanical loosening of that device. In infected prosthetic joints, loosening causes additional pain and generates 'wear particles' of metal and acrylic cement, which themselves cause more inflammation (Panday et al. 1996). In infections of fracture-fixations and fusions, loosening leads to instability and increased risk of nonunion. In both situations, loosening also appears to further reduce resistance of the immediate environment to infection, making control of infection more difficult.

MOLECULAR BASIS OF BONE RESORPTION

There have been considerable advances in our understanding of the process by which bone is resorbed in health and disease. Central in this is the osteoclast, which differentiates from monocytic precursor cells in response to a range of endocrine and paracrine signals. Osteoclasts form tight associations with underlying bone, and acidify a physical compartment beneath them, leading to bone resorption (Panday et al. 1996). In vitro, this results in a visible pit on the surface of the bone, and the release of calcium into the medium, either of which can be measured. Using models of this type, the response of osteoclasts to bacterial products has been studied. Cell-associated materials eluted from a number of different bacteria trigger osteoclast activity. In the case of *Mycobacterium tuberculosis*, the chaperonin Hsp 60 is a potent stimulant. Less well-characterized constituents associated with the cell walls of *Staphylococcus aureus* and *Staphylococcus epidermidis* also stimulate resorption, though intriguingly, by different mechanisms as demonstrated by the effects of prostaglandin inhibitors (Meghji et al. 1997).

CELL AND MOLECULAR BASIS OF JOINT DESTRUCTION

Improved understanding in this area owes much to the systematic use of a rodent model of hematogenous septic arthritis induced by tail vein challenge with *Staphylococcus aureus*. This model has proved tractable to manipulation using a range of knockout mice, cytokine antagonists, and varying triggers of articular inflammation (Tarkowski et al. 2002). Clear themes emerging from this large body of work are that the inflammatory response protects the host from septicemic death, but is the major mechanism of articular cartilage destruction. T cells play a major role in this, and their actions are orchestrated by inflammatory cytokines such as TNF. T cell responses are triggered by CpG motifs in bacterial DNA (Deng and Tarkowski 2000) and by peptidoglycan cell wall components (Liu et al. 2001). Downmodulation of inflammatory response protects the infected joint, but only if antibiotics are used to keep the whole animal alive. In addition to demonstrating this in complex situations such as mice defective in adhesion molecules critical for immune function, such as intercellular adhesion molecule-1 (ICAM-1) (Verdrengh et al. 1996), it has also been shown that steroid therapy, if combined with antibiotics, reduces joint destruction, a finding that may be of clinical relevance (Odio et al. 2003).

MICROBIOLOGY

Despite the wide range of bacteria that are known to infect bone, *Staphylococcus aureus* stands as the preeminent cause of these infections (Bouza and Munoz 1999). It is the dominant cause of hematogenous and contiguous focus bone and joint infections. The bulk of hematogenous infections are monomicrobial. In addition to *Staphylococcus aureus*, aerobic gram-negative rods and group B β-hemolytic streptococci play important roles in neonatal infections; in children group A β-hemolytic streptococci, *Kingella kingae* (Birgisson et al. 1997; Dodman et al. 2000) (and in the unimmunized child, *Haemophilus influenzae* type B (HIB) though vaccine use has led to dramatic falls in the incidence of this (Bowerman et al. 1997)); *Salmonella* spp. in those with sickle cell anemia. Chronic infections complicating orthopedic devices have a preponderance of coagulase-negative staphylococci as causes (Christensen et al. 1994), but *Staphylococcus aureus*, including MRSA, remains important in acute device-related infection. In contiguous focus infections secondary to chronic soft tissue loss, infections are commonly polymicrobial, with aerobic gram-negative rods (mainly the Enterobacteriaciae and *Pseudomonas* spp.), anaerobes and enterococci represented alongside *Staphylococcus aureus*. This includes not only osteomyelitis complicating decubitus and diabetic foot ulcers, but also chronic osteomyelitis and prosthetic joint infection when draining sinuses have been present for prolonged periods of time. Gram-negative aerobes also play an important role in vertebral osteomyelitis in the elderly, presumably because of the increased rates of bacteremia secondary to more frequent urinary tract and intra-abdominal infection.

Clearly other pathogens may be of importance. *Mycobacterium tuberculosis* is the commonest worldwide cause of chronic septic arthritis and is of importance elsewhere in the skeleton, notably in the spine (Potts disease). Where endemic, *Brucella* spp. are also relatively common causes of infective spondylitis and septic arthritis (Sankaran-Kutty et al. 1991; Geyik et al. 2002). Brucellosis, Lyme disease (Franz and Krause 2003), and gonococcal infection (Bardin 2003) should always be considered in culture negative cases of septic arthritis. Appropriate epidemiological risk factors should be enquired after in culture-negative cases, or when the pathogens are distinctively unusual. Reports of osteomyelitis caused by *Salmonella arizonae*, linked to pet reptiles, are good examples of how individual risk factors can be identified and used in subsequent public health awareness (Nowinski and Albert 2000; Nowinski 2001).

In addition to the common, there is a long list of rare causes of bone and joint infection, including *Listeria* spp. (Mereghetti et al. 1998), pneumococci (Ispahani et al. 1999; Ross et al. 2003), *Pasteurella* spp. (Shapero and Fox 1999), *Fusobacterium* (Koornstra et al. 1998), and *Tropheryma whipplei* (Lange and Teichmann 2003). This fact is important only because it emphasizes the need for a rational approach to microbiological diagnosis and empiric treatment. Essentially any organism capable of causing a bacteremia or a soft tissue infection can occa-

sionally involve skeletal structures, including atypical mycobacteria (Clark et al. 1997; Ekerot et al. 1998), *Nocardia* spp. (Wilkerson et al. 1985; Ostrum 1993) and *Actinomyces* spp. The compromise to local host responses caused by an implanted device or by debris means that a wide range of environmental or low virulence pathogens are, from time to time, implicated in infections related to prosthetic joints, fracture fixations, and puncture wounds. Although coagulase-negative staphylococci are the prime movers in this regard (Christensen et al. 1994), many other organisms including *Clostridium difficile*, *Pasteurella* (Takwale et al. 1997) *Listeria*, *Brucella* (Malizos et al. 1997; Orti et al. 1997), corynebacteria (von Graevenitz et al. 1998), *Mycobacterium tuberculosis* (Berbari et al. 1998b) and other mycobacteria (Guerra et al. 1998) have been identified. Probably the most common atypical pathogen in this context, and a paradigm for the interaction between environmental contamination and host compromise, would be the high incidence of osteochondritis, progressing to osteomyelitis, caused by *Pseudomonas aeruginosa* in puncture wounds of the foot associated with the wearing of training shoes (sneakers) (Fisher et al. 1985; Niall et al. 1997). High densities of *Pseudomonas aeruginosa* living in the insole allow for inoculation into the weight bearing area of the foot if a nail penetrates the foot through the shoe. There is frequently also some debris present in addition to the bacterial contamination (Chang et al. 2001), and the result is that a pathogen normally only associated with significant host compromise is able to cause a potentially serious infection in an otherwise healthy individual (usually a child).

PREVENTION

Given that no vaccines yet exist against most of the causes of skeletal infection, prevention is geared at restricting the access of organisms to exposed bone or orthopedic implants (Norden 1985). This means taking measures to prevent the breakdown and infection of soft tissue in the at-risk patient; preventing pressure ulcers through risk assessment and risk reduction in hospitalized, bed-bound and other immobile persons, organizing foot care programs for diabetics, and taking measures to prevent surgical wound and deep infection after orthopedic surgery or trauma (Gillespie 1997). The latter include meticulous sterile theater technique, the use of ultraclean air for implant work, prophylactic antibiotics (chosen with regard to local sensitivity patterns among key pathogens) (Glenny and Song 1999), and careful handling of tissues to minimize necrosis and hematoma formation. Preventive measures of this kind involve considerable effort, and regular feedback of results to clinical teams is essential.

Post-operative hematomas need to be drained (Saleh et al. 2002), while leaking and clinically infected wounds should be explored (to prevent the development of deeper infection, or to diagnose it early and minimize the risk of progression to more severe or chronic disease). Traumatic wounds need careful exploration and debridement of devitalized tissue and debris, with priority given to early soft tissue cover of fractures with the involvement of plastic surgeons if necessary (Gustilo and Anderson 1976; Khatod et al. 2003). The relationship of some cases of hematogenous septic arthritis and osteomyelitis to episodes of clinically apparent bacteremia also implies that general measures to reduce staphylococcal bacteremia associated with intravascular catheterization (through appropriate infection control measures) would be valuable, though proof of efficacy would be hard to establish.

There is considerable interest at present in the cell wall-associated adhesins as potential vaccine candidates, hoping that specific antibody might be able to play a role in preventing localization of infection to deeper structures (Flock 1999). Progress is encouraging (Nilsson et al. 1998), but has not yet translated into clinically applied products.

Finally, one specific area for prevention concerns the implantation of prosthetic joints in patients with histories of prior septic arthritis or osteomyelitis, including osteoarticular tuberculosis (Lee et al. 2002; Kim et al. 2003). There is some evidence based on case series that joint replacement can reactivate tuberculosis or pyogenic infection (Wang 1997; Su et al. 1996). Active infection should ideally be treated before joint replacement is undertaken (Hardinge et al. 1979; Jupiter et al. 1981). Where this is impossible, or where the history is recent (raising the suspicion that cultures will in fact be positive), it may be necessary to stage the joint replacement, resecting the infected area, treating according to the results of cultures, and implanting the joint replacement after an interval (Nazarian et al. 2003). However, some centers have described acceptable results using a single stage approach, antibiotic loaded cement, and systemic therapy.

CLINICAL FEATURES

Skeletal infections, as seen above, cause local and sometimes systemic features, together with destruction of bone and joint (irrespective of attempts at preservation of function), and have the potential rapidly to establish chronic active infection. Clinical features are in keeping with these characteristics, notably pain, loss of function, acute inflammatory changes in overlying soft tissue, systemic illness due either to bacteremia or to chronic suppuration, sinus tract drainage, and progressive soft tissue and osteoarticular destruction. There may be other local complications, such as spinal cord or nerve root compromise from vertebral osteomyelitis when there is complicating epidural abscess (Baker et al. 1975), retropulsion of infected disk material, or mechanical instability. Pathological fracture, growth plate distur-

bance, or secondary septic arthritis may complicate osteomyelitis; soft tissue abscesses frequently develop during the evolution of undiagnosed or untreated acute osteomyelitis and are also commonly found in the context of infected metal ware.

When joints are infected, the features are of pain, swelling, and considerable reluctance to undergo active or passive movement. Joint effusion is followed by the development of synovitis, which may persist for weeks after successful treatment of the infection. If the diagnosis is missed or delayed, or treatment unsuccessful, progressive joint destruction ensues, with increased pain and disability.

The evolution of acute to chronic osteomyelitis has been detailed above. Acute osteomyelitis classically presents as a prostrating febrile illness with pain in a long bone. In the young, this may manifest simply as refusal to use the affected limb. There may be little in the way of soft tissue change, though edema and eventually abscess formation will develop once infection tracks from the interior of the bone out through the cortex. Some 50 percent of cases of acute osteomyelitis have an accompanying bacteremia. Chronic osteomyelitis much more commonly has suspicious features visible in the soft tissues, whether this is a chronic wound or ulcer overlying bone, a sinus tract or simply old scars that indicate previous surgery or episodes of drainage. Chronic osteomyelitis presents with fever rarely, unless a collection of pus has been trapped through premature sinus closure, or has not yet discharged since a recurrence began. Bone may be visibly exposed in chronic osteomyelitis, be unexpectedly palpated with a gloved finger on inspection of a pressure sore, or be identified by palpation with a sterile metal probe, which in diabetic foot ulcers is moderately predictive of underlying osteomyelitis (Grayson et al. 1995a).

DIAGNOSIS

General principles underlying diagnosis, including the desirability of understanding the performance and limitations of specific tests, are taken as understood and are dealt with elsewhere in this text. These considerations are of particular importance in relation to imaging studies and the interpretation of cultures, where there are significant problems with sensitivity and specificity to consider. One important point that must be made, however, is that there is a relative shortage of high-quality diagnostic studies, despite a considerable number of publications. Part of the problem is a lack of understanding of the requirements of studies aiming to assess a diagnostic test rigorously. But part too is a lack of consensus definitions of osteomyelitis or prosthetic joint infection, such that although expert clinicians would recognize most of these infections when they saw them, they would not necessarily agree on the formal requirements for making the diagnosis. Imprecision in this matter makes it hard to interpret the majority of studies once the goal is to compare one study with another. This problem besets all the diagnostic modalities that will be discussed below, and must constantly be borne in mind.

Clinical features

Clinical suspicion is of paramount importance in arriving at a diagnosis. Certain features, such as sinus tract formation, are pathognomonic of infection. More commonly, clinical features are nonspecific (pain, loss of function, soft tissue swelling, even fever) and are sometimes insensitive, for example in chronic prosthetic joint or diabetic foot infection (Lavery et al. 1996). It follows that a high level of clinical suspicion for infection must be maintained whenever patients present with acute changes in musculoskeletal function, especially if accompanied by fever; with unexplained pain, stiffness or soft tissue swelling; with destructive bony lesions especially if accompanied by reparative responses; or whenever orthopedic implants fail rapidly with no obvious technical explanation. Night pain is indicative of very significant inflammation and is a warning symptom; pain on first using a prosthetic joint that eases as the joint is used, only to return after each period of rest (so-called 'start-up' pain) is highly suggestive of loosening; and some patients with chronic osteomyelitis will complain that the severity of bone pain is linked to changes in the weather. But none of these features is universal or pathognomonic for infection, and so the diagnosis must rest on recognizing the possibility, and taking the necessary steps, to confirm or refute infection within an appropriate timescale depending on the nature of the diagnosis being entertained. For acute presentations in which early intervention is key in preventing damage and chronicity, diagnosis must be expedited and may even need to follow on from the initiation of treatment. For chronic conditions there is rarely urgency to make the diagnosis or commence treatment unless the differential diagnosis of a tumor is a significant possibility.

Laboratory

Most laboratory studies provide only supportive information alongside the clinical impression. With the exception of serological testing for minority causes of infection such as *Brucella* spp., tests are nonspecific. Measurement of full blood count may reveal anemia of chronic disease. Acute phase responses (elevations of white cell count and C-reactive protein (CRP)) are generally elevated in acute septic arthritis and acute osteomyelitis or if a deep abscess containing a high-grade pathogen has formed. Elevations in the erythrocyte sedimentation rate are often seen, and if no other cause is found, support a diagnosis of osteomyelitis.

Generally, more chronic infections are associated with less perturbation of the inflammatory markers, a feature also commonly seen in diabetic foot infections, where fever and elevations in white cell count are indicative of more severe disease, with many infections not eliciting a strong systemic response (Edelson et al. 1996).

There are no other generally accepted serological diagnostic tests for pathogens prevalent in bone and joint infection. Serodiagnosis of prosthetic joint infection using antibody responses to glyocalyx has been put forward, but has yet to be widely validated and adopted. The majority of pathogens diagnosable by current serological techniques are exceedingly rare causes of bone and joint infection, and so the use of these tests cannot be justified in routine practice, though specific clinical indications may make them relevant.

Imaging

The aims of diagnostic imaging are both to diagnose infection and ultimately to delineate its anatomical extent (Santiago Restrepo et al. 2003). Few single modalities provide all the required information, and all have flaws in their performance depending on the circumstances of the case.

Figure 1 *Plain radiograph of femur with chronic osteomyelitis present. A minor periosteal reaction is seen, but no other changes.*

Plain XR

Plain radiological abnormalities take time to develop; in the case of bone this is several days for sufficient bone to be resorbed or to form to the extent that it becomes visible. The first signs of acute osteomyelitis are soft tissue swelling, followed at 7–10 days by the development of lucency. When periosteal reaction produces new bone, it is not visible for 10–14 days. For this reason, a single normal radiograph does not rule out an acute osteomyelitis. A chronic osteomyelitis is generally identifiable from the mixed picture of lucency and periosteal reaction (Figure 1). Serial films are useful, because osteomyelitis is an aggressive process that generally shows rapid evolution. An evolving mixed destructive and reparative picture is highly suspicious of active infection.

The location of the lesion depends on the chronicity, the age of presentation and the specific manifestation. Acute childhood osteomyelitis is a metaphyseal disease, but the skeletal abnormality will become increasingly diaphyseal as the bone grows, with the growth plate moving away from the old focus of infection. Ongoing activity or episodes of recurrence will maintain a metaphyseal component to the lesion. More active disease is characterized by 'fluffiness' of the periosteal reaction and of the margins of bony lucencies. Healed infection has much 'crisper' margins, with the periosteal reaction being fully organized into involucrum, and lucent areas either being filled in again or becoming more demarcated. Some subacute forms of infection present with obvious cavities within bone, classically surrounded by a sclerotic rim (the whole known as a Brodie's abscess). Even more indolent presentations are found in the form of chronic multifocal osteomyelitis, a poorly understood condition in which cultures are negative, and multiple sites may be involved over a period of time, generally without the kind of progressive destruction usually seen in osteomyelitis, but with intense sclerotic changes in bone and expansion of the bone due to chronic periosteal reaction (Kozlowski et al. 1983; Golla et al. 2002; Huber et al. 2002).

Bony changes in septic arthritis consist of accelerated arthritis with loss of joint space and secondary changes in the underlying bone. In hip or shoulder, there may be avascular necrosis of the femoral or humeral heads, with collapse.

In prosthetic joint infection, the cardinal features are the development of lucency at the bone–cement interface. This reflects loss of bone due to chronic inflammation, and its replacement, at the interface, with connective tissue (so-called 'membrane') that is edematous, hyperemic, and inflamed. As loosening progresses, mechanical failure of one or both components can occur. In hip replacements, one may see evidence of rotation of the acetabular component, or cortical erosion at the tip of the femoral component ultimately leading to femoral fracture. In knee replacement, the tibial component may collapse into valgus or varus.

Although the changes outlined here are consistent with infection, they are rarely diagnostic. In long bones,

the differential diagnosis of tumor must always be borne in mind, while in prosthetic joints it is the accelerated timescale that is particularly suggestive of infection; the changes of loosening are nonspecific and may occur in the absence of infection. In diabetic foot disease, neuropathy can lead to changes in bone and joint; healed fractures, subluxation with secondary degenerative changes, and sometimes of a destructive nature including acute Charcot (neuropathic) arthropathy. The appearances of this diabetic neuro-osteoarthropathy can easily be mistaken for infection.

Ultrasound

Appropriately powered ultrasound can obtain relatively good images of many external parts of the skeleton. Sinus tracts can be identified and followed down to likely points of origin on bone or prosthesis. Collections can be imaged, and periosteal elevation can frequently be seen. Cellulitis or edema within deeper structures (muscle) can be visualized and joint effusions distinguished from synovitis. Ultrasound, if available, can therefore play an important role in the management of acute osteomyelitis, identifying a subperiosteal abscess, the early periosteal edema consistent with the evolution of one, or an abscess that has already tracked out into the soft tissues (Kaiser and Rosenborg 1994; Mah et al. 1994; Cardinal et al. 2001). Diagnostic aspiration under guidance may be possible, and this application is also of great value in attempting to obtain a microbiological diagnosis in suspected or proven prosthetic joint infection, and sometimes in chronic osteomyelitis.

Isotope scanning

The history of nuclear medicine in osteoarticular infection encompasses several isotope scans that have failed to live up to early enthusiasm. The fundamental problem is the relatively nonspecific nature of musculoskeletal responses as currently detected. Noninfective processes such as diabetic neuro-osteoarthropathy, fracture nonunion, and prosthesis loosening, also generate abnormal scans (Turpin and Lambert 2001). The need for high levels of sensitivity and specificity has not yet been met reliably, despite studies with triple-phase Technetium bone scanning (sensitive but very nonspecific) (Schauwecker 1992), Indium-labeled white scan (more specific but less sensitive, and so sometimes combined with conventional bone scan) (Johnson et al. 1996), marrow colloid scan (designed to exclude marrow white cell packing as a confounding cause of false positive white cell scans), labeled immunoglobulins and anti-white cell monoclonal antibody scans (Palestro et al. 2003), and Technetium-labeled white cell scans (Devillers et al. 1995) (designed, in different ways, also to localize the white cells present in inflammatory lesions). Of all currently available isotope scanning protocols, the greatest specificity can be obtained with the combination of indium white cell scanning and nanocolloid scan; alternative labeling techniques for white cells may offer promise. White cell labeling scans are not trivial matters, however, given the need to remove, purify, label, and reinfuse white cells, which opens up obvious possibilities of infection and cross-infection. For prosthetic joint infection, no scan is recommended; for acute osteomyelitis in the otherwise normal skeleton (e.g. in childhood) triple phase bone scan (Figure 2) may be an acceptable confirmatory test that will follow a clinical decision to treat; for chronic osteomyelitis, a labeled white cell scan combined with nanocolloid scanning is acceptable if magnetic resonance imaging (MRI) is unavailable.

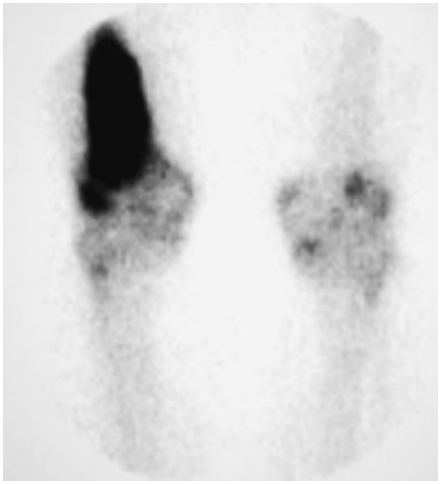

Figure 2 *Triple phase bone scan (bone phase) showing intense uptake*

MRI

MRI is able to produce images in axial, sagittal, and coronal planes, and gives information that is physiologically derived (based on fat and water content of tissues) but anatomically portrayed. With few exceptions, it is the imaging modality of first choice in bone and joint infection. It will show soft tissue edema and fluid collections; cortical breaches in bone; edema (Figure 3 and 4), abscess and gas within bone; and through gadolinium enhancement, will distinguish inflammatory from noninflammatory high signal. By demonstrating intraosseous edema, it can diagnose osteomyelitis before plain radiological changes are evident, and is also of great value in assessing relapse in cases of chronic osteomyelitis, where plain films are already abnormal. In some areas, such as the spine, MRI has transformed the diagnosis of infection, with superior simultaneous resolution of disk space, paravertebral structures, nerve root foraminae, epidural space (important in identifying epidural abscess) and the anterior and posterior bony columns.

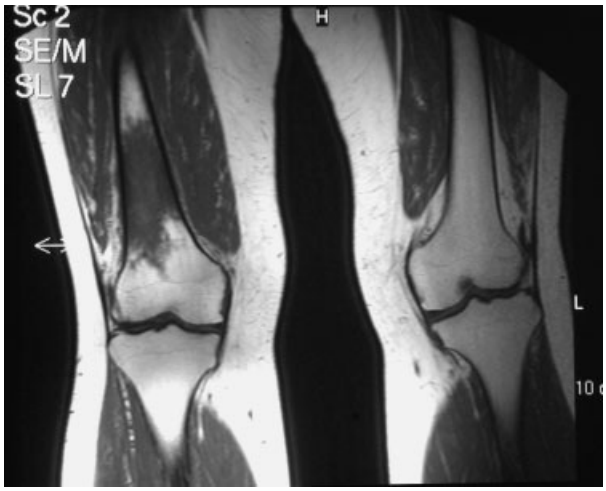

Figure 3 *T1 weighted MRI scan of the same region as in Figure 1, showing intramedullary edema as low signal*

MRI does suffer some pitfalls, notably when there has been previous surgery, when follow-up scans are performed after treatment of infection (images take many months to return to normal after either) or when metal is or has been present. Titanium implants produce minimal signal void, but more standard materials can produce dramatic metal artefact, even when the metal ware has long been removed (small amounts of metallosis in the tissues being enough to disrupt the image).

Figure 4 *T2 weighted MRI scan (STIR) of the same region as in Figure 1, showing intramedullary edema as high signal. Additionally, high signal periosteal reaction is seen.*

There are also problems in the interpretation of diabetic foot osteomyelitis, where underlying neuro-osteoarthropathy can mislead the unwary; some stress-related bone marrow changes and bony fragmentation are to be expected, and do not necessarily indicate infection with as much reliability as in the non-neuropathic patient. Overall, however, when available, MRI is of great value in suspected acute osteomyelitis (as a confirmatory test after the onset of treatment) and in chronic osteomyelitis (assessment of activity and surgical planning). Its role in prosthetic joint infection is minimal because the primary interest is at the bone–cement interface, which is usually affected by signal void, though occasionally distant collections or osteomyelitis can be identified.

Culture

This is clearly the 'gold' or criterion standard in the diagnosis of almost all infections, excepting only those rare cases caused by nonculturable organisms. The major issues that beset bacterial culture are as follows.

LACK OF SENSITIVITY OF STANDARD METHODS OF SAMPLING AND OF CULTURE

Some 15 percent of prosthetic joint infections, and a similar proportion of cases of chronic osteomyelitis, are culture-negative, yet show histological signs of active infection (Atkins et al. 1998). One potential explanation is the very low densities of organisms in some manifestations of infection. Experimental studies in animal models suggest that the density of bacteria in periprosthetic tissues is considerably lower than the density in an acute abscess, and explains why a swab of fluid near the implant or infected bone will not always yield a useful result. To increase sensitivity, a number of pieces of the periprosthetic tissues should be obtained for culture, and the culture routine should include cooked meat broth or an alternative enrichment medium that is supportive to damaged and fastidious organisms (Atkins et al. 1998). To increase specificity, each sample should be taken with a separate set of instruments to avoid cross-contamination between sampling. A carefully conducted prospective study of hip and knee replacements undergoing revision, suggested high levels of both sensitivity and specificity can be achieved through this rigorous multiple sampling approach (Atkins et al. 1998). Other approaches have focused on increasing the yield from cultures by using ultrasonication to dislodge organisms from the surface of the explanted prosthesis. This has suggested that the presence of bacteria is greatly underestimated in loose prostheses, but the work currently awaits independent confirmation.

INTERPRETATION OF POSITIVE AND MIXED CULTURE RESULTS

Many infections are active in the context of chronic wounds that overlie the involved bone or prosthesis. The

wound will acquire a dynamic flora of its own, and irrespective of the original pathogens, secondary ones may establish themselves in the bone after prolonged access via the wound. In our experience, a transition from gram-positive to gram-negative pathogen, or from methicillin-sensitive gram-positive, to methicillin- (and occasionally vancomycin-) resistant gram-positive pathogen is frequently seen. Antibiotic selection is an important cause of this dynamic evolution.

How to interpret microbiology results in this situation is problematic. Studies suggest that superficial cultures are misleading and poorly predictive of the deep flora (Mackowiak et al. 1978). The microbiologist is therefore dependent upon sensible sampling behavior and accurate specimen labeling by the surgeon. Wounds should be thoroughly debrided before cultures are sent, or cultures obtained through a quite separate, uninfected field, as with a percutaneous biopsy. The surgeon must understand the crucial importance of cross-contamination. Tissue samples should be encouraged over swabs, which do not facilitate the isolation of anaerobes. Material must be sent to the laboratory without delay. Results should be fed back to surgeons in person as often as is possible, to allow discussion of therapeutic options and to reinforce joint working with the specialist in infection. Where the pathogens are not distinct from the likely skin or ulcer flora, and the biopsies have had to come through this field, a good rule of thumb is to demand the isolation of an indistinguishable organism (by biochemical identity and antibiogram) in at least two independent samples. Confirmatory histological examination of tissue is also invaluable.

Histology

The majority of pyogenic infections cause an acute inflammatory response. This is in contrast, in the skeleton, with conditions that give more chronic inflammation, where the inflammatory response shows remarkably few neutrophils. It is possible to distinguish infected from uninfected periprosthetic tissue with considerable accuracy, mainly on the basis of the numbers of infiltrating polymorphs (Mirra et al. 1982; Panday et al. 2000). This forms the basis of being able to diagnose infection in a prosthetic joint in real time, using frozen section, during joint revision surgery (Fehring and McAlister 1994; Athanasou et al. 1995; Lonner et al. 1996). It also provides an essential second diagnostic modality to match up with cultures in all contexts (White et al. 1995). The importance of this should be stressed, as it is not unknown for lesions that do not respond to appropriate treatment for infection to turn out to be tumors. In some situations, either because of sampling error, prior antibiotic use or presumed fastidious organisms, histology suggestive of infection may be the only evidence available, because the cultures are negative (White et al. 1995). Histology is also of great importance in the diagnosis of mycobacterial disease, given the slowness of culture results in most mycobacterial infections.

Polymerase chain reaction

The use of polymerase chain reaction (PCR) for diagnosis is appealing given the limitations in sensitivity of conventional culture. There are surprisingly few published studies in this area, suggesting that researchers are encountering significant technical difficulties in achieving a robust and reproducible test. Using a universal primer for the 16S rRNA gene, an early study suggested that a substantial number of culture-negative explanted prostheses had evidence of bacterial DNA on PCR, but with an incomplete correlation between a positive conventional culture and a positive PCR (Mariani et al. 1996; Hoeffel et al. 1999). Other studies have shown detection of bacterial DNA, but have not evaluated this as a formal diagnostic test (Tunney et al. 1999). Although an absolute indicator of infection would be useful to answer certain clinical questions, an identity and preferably an antibiogram are both of importance in definitive treatment planning, so more sophisticated techniques may ultimately have to be employed.

TREATMENT

The fundamental principles of treatment follow on from the special features of pathogenesis outlined earlier. Treatment of acute presentations must be prompt, effective, and predicated on appropriate empiric antibiotics based on clinical suspicion. The aim in acute cases is to prevent the progression to chronicity, via the death of bone, with its correspondingly worse prognosis. Provided treatment is effective and timely, it often does not need to be protracted. The use of clear guidelines and protocols can help ensure consistent treatment approaches to acute infections (Peltola et al. 1997; Levy et al. 2000; Kocher et al. 2003).

Treatment of chronic presentations is based on the principles of establishing a clear microbiological diagnosis, using histology in parallel; excising dead and foreign infected tissue; establishing soft tissue cover and skeletal stability; managing surgical dead space; preserving functional implants where possible while they are necessary; using appropriate antibiotics for often extended periods of time, according to the biology of the infection and the host; and carrying out further reconstructive surgery, usually when infection is controlled. For all forms of chronic bone and joint infection, it is important to set realistic goals and expectations, which must include the possibility of recurrence and plans for the management of such an eventuality.

In treating infected orthopedic implants, the principles are a fusion of the two. For acute infections, urgent appropriate diagnosis and treatment is needed, aimed at preventing chronic infection, often with retention of the implant if still functional. For chronic infections, a more measured approach is required in which realistic goals are set with the patient, reconstructive options considered and a treatment plan delivered as with other chronic skeletal infections.

Surgical treatment

This is a key element of successful treatment in most situations, especially in chronic cases. In acute osteomyelitis and in vertebral osteomyelitis, provided there are no collections or abscesses, surgery can be deferred and may not be needed. Indeed, in acute osteomyelitis, gratuitous windowing or drilling of cortical bone, in the absence of other evidence of intramedullary abscess, is no longer in favor among most surgeons. In all other situations of chronic osteomyelitis, with the possible exception of the diabetic foot with its predominant involvement of small bones, surgical removal of dead infected bone is crucial.

Debridement and excision

Careful exploration of infected tissues allows determination of the extent of infection, scarring, abnormal soft tissue, and bone, and hence permits decisions about the degree of resection needed. The aim should be that at the end of surgery, bone at the resection margins is viable as indicated by bleeding, provided this leaves a limb that is either still functional or is reconstructable. Recurrent infection is often linked to failures of resection. In chronic prosthetic joint infection, the same thinking applies. The prosthesis and all cement, infected soft tissue, and dead bone should be removed, and abscesses drained. Rarely, it is appropriate to attempt salvage of a chronically infected prosthetic joint, if solidly fixed, pain free, and in situations where the expected morbidity of revision surgery exceeds that of ongoing infection and long-term antibiotics (see below). This is a more standard approach in an acute infection with a well-fixed prosthesis, where the damage caused by removal of the implant may be significant, and where studies show success rates of 50–70 percent if the debridement is thorough and timely (Brandt et al. 1997; Mont et al. 1997; Crockarell et al. 1998; Tattevin et al. 1999; Krasin et al. 2001).

Soft tissue cover

Some failures of osteomyelitis management are linked to persisting soft tissue defects or areas of extensive (and by definition relatively avascular) scar tissue. A tissue defect takes a prolonged period of time to heal and in some cases cannot (for example, when it overlies extensive dead bone or metal ware), while scar tissue limits the access of inflammatory mediators and antimicrobials to the infected area. Fortunately, modern plastic surgical techniques allow for the transposition of skeletal muscle with the corresponding vascular pedicle, using microvascular anastomosis, into tissue defects (Kuokkanen et al. 2002). Muscle flaps provide healthy, well-vascularized soft tissue cover and the physical characteristics of muscle make it ideal for laying into a bony defect, to the walls of which it rapidly adheres. Alternatively, muscle can be moved through lateral release or rotation upon the vascular pedicle, in this context most commonly in the case of the gastrocnemius, one head of which can be tunneled anteriorly to provide cover for the knee (McPherson et al. 1997; Casanova et al. 2001). This is of crucial value when wound breakdown compromises the soft tissue over a knee replacement, either acutely to aid implant salvage, or as part of a revision strategy.

Dead space management and reconstruction

Surgical ‘dead spaces’, namely cavities in tissue that are left to fill with blood, exudate or serous fluid, are risk factors for renewed or recurrent infection. Elimination of these dead spaces is an additional priority of surgical technique. Muscle flaps are excellent means of dead space management, but other means are sometimes employed. These include antibiotic loaded acrylic bone cement, which combines antibiotic delivery with dead space management. This can be combined with subsequent bone grafting if required, either for structural indications or to eliminate larger cavities definitively (McNally et al. 1993; Alonge et al. 2002).

Reconstructive options depend upon the specific situation. Fracture non-unions require stabilization; external fixation is generally preferred, to avoid instrumenting an already infected field, but the key priority is effective stabilization, which is essential for comfort, for union to proceed, and it seems, for control of infection.

For prosthetic joints that have been removed, reconstructive options rest with reimplanting a new joint, fusing the joint, or leaving an excision arthroplasty. In the hip, the latter results in a Girdlestone’s pseudarthrosis, which is compatible with function in most patients, albeit with walking aids; for the other major joints, excision is a relatively poor option. For reimplantation, there is significant uncertainty over the choice between one- and two-stage revision surgery (Buchholz et al. 1981; McDonald et al. 1989; Raut et al., 1995; Goldman et al. 1996; Younger et al. 1997; Haddad et al., 2000). The one-stage technique is favored when highly sensitive organisms infect relatively healthy hosts, with two-stage revision favored for less fit hosts and more

resistant bacteria (Hanssen and Osmon 2000; Fisman et al. 2001). Frustratingly, it is precisely in the less fit patient that one stage revision is most inherently attractive, to avoid the considerable morbidities of spending weeks without the function afforded by a functioning prosthesis, and of a second general anesthetic. For many, this limits the usefulness of the one-stage concept (Jackson and Schmalzried 2000), especially in view of difficulties in defining the infecting pathogen before definitive surgery. Some go so far as to take additional samples at the end of the first stage and accompanying antibiotic treatment, to determine whether to carry out additional debridements prior to reimplantation (Mont et al. 1997).

One important advance has been in the management of segmental defects of long bones using the Ilizarov method. This involves external stabilization of the limb using fine wires traversing the bone, attached to circular rings. A number of such rings, arrayed axially along the limb, are linked by longitudinal rods, and the resulting frame stabilizes the limb. The power of this method is that it is possible not only to remove an entire segment of bone, but also to grow new bone. By creating a corticotomy through bone adjacent to the defect, a viable segment can be produced that is itself stabilized by wires and a ring as part of the frame. By altering the relative positions of the rings, this 'transport segment' can be moved through the defect, a few millimeters a day, until it is 'docked' at the far end of the bone defect. The traction on the intact periosteum at the corticotomy site results in new bone formation. Using the method, large segmental defects can be regenerated with healthy bone of normal structure.

Antimicrobial treatment

Although bone infection can be managed without antibiotics, relapse rates were high in the pre-antibiotic era. Furthermore, the prolonged nature of resection and reconstruction surgery would lead to a high postoperative infection rate, highly likely to involve the surgically injured bone. Despite the rise in antibiotic resistance, there are still several good drugs available for use in osteomyelitis. The historical standard of care is prolonged intravenous therapy, but there is growing confidence in the use of shorter treatment regimens and highly bioavailable oral therapies in some situations (Kim et al. 2000; Jaberi et al. 2002; Le Saux et al. 2002; Vinod et al. 2002), alongside technologies that permit early discharge from hospital despite a decision to continue parenteral treatment.

It is notable that relatively few antibiotics have specific licensed indications for either osteomyelitis or prosthetic joint infection. This is more a reflection of the high costs and risks to pharmaceutical companies (in seeking indications for treatment in conditions that require prolonged treatment and may still have appreciable failure rates) than an indication that the drugs inherently will not work. Although the literature frequently raises the issue of 'bone penetration', there are uncertainties about the meaning and relevance of this term. Measuring antibiotic levels in cortical and cancellous bone, accounting for the levels within marrow stroma, and understanding whether the key targets of antibiotics are in the interstitial fluid, the bony matrix, or even the cellular elements within bone are all topics fraught with difficulty.

It has been hard to escape the view that in the antibiotic era, it has not been the development of drugs with bone penetration, but the renewed understanding of the critical nature of adequate surgical resection, and improvements in reconstructive techniques, that have led to improved outcomes for many with chronic infection. Nonetheless, antibiotics are still rightly regarded as a key element of treatment, even though a meta-analysis of published studies concluded that there is insufficient evidence to favor one drug, route of administration or duration over another (Stengel et al. 2001). They do play a pivotal role in treating those manifestations of infection not amenable to surgical excision; acute infections where bone and joint destruction have not yet occurred, and where a decision is made to undertake long-term suppression of the infection, with implant retention (Segreti et al. 1998; Tattevin et al. 1999). This strategy has been useful in acute prosthetic joint infection, and seems particularly likely to succeed when there is a short interval (48 hours or less) between onset of symptoms and the surgical debridement (Brandt et al. 1997; Mont et al. 1997; Crockarell et al. 1998; Krasin et al. 2001).

Systemic: intravenous

The lack of oral bioavailability of many β-lactam antibiotics, aminoglycosides, and glycopeptides, make them good choices for intravenous therapy against many gram-positive organisms. In many situations, such as prosthetic joint infection and some cases of osteomyelitis, courses of intravenous therapy of 4–6 weeks duration are commonplace. This requires the placement of central venous access, most commonly with a tunneled subclavian (Hickman or Broviac) line, but increasingly with peripherally inserted central catheters (PICC) (Parker and Gaines 1995) or shorter lines terminating in the axillary vein, so-called 'mid'-lines. The dependable nature of such vascular access means that they can be used to underpin programs for administration of intravenous antibiotics in the home or outpatient setting (Grayson et al. 1995b). Ceftriaxone and teicoplanin are useful drugs in this regard because of their once-daily dosing regimens, but more frequent dosing is possible, especially if patients can be taught to self-administer,

and various technologies permit the use of drugs that must be delivered by continuous or intermittent infusion if need be. Recent analysis indicates a high success rate in cases of osteomyelitis treated with prolonged courses of ceftriaxone (Tice et al. 2003). Outpatient parenteral antibiotic therapy (OPAT), outpatient and home parenteral antibiotic therapy (OHPAT) and a number of other acronyms describe this mode of treatment, which is in established use in many centers around the world (Bernard et al. 2001). Osteomyelitis and prosthetic joint infection patients are major users of such programs.

Systemic: oral

Although the availability of OPAT transforms the prospects for giving prolonged intravenous treatment (in an era when prolonged hospital stays are, in the main, neither culturally nor financially acceptable), there are obvious issues about the costs and risks of intravenous therapy. There is now a range of highly bioavailable oral therapies, many of which are used in the treatment of osteomyelitis or prosthetic joint infection (Shuford and Steckelberg 2003). With the exception of first-generation cephalosporins, the orally available drugs do not act on the bacterial cell wall but on DNA or protein metabolism. The nature of these targets is, in the main, associated with easier acquisition of resistance, and it is important to bear this in mind in selecting treatment, especially if there is a high bioburden of infection at the start (for example, when debridement surgery is not carried out). Useful drugs include high-dose trimethoprim-sulfamethoxazole, doxycycline, rifampin, and fusidic acid for staphylococci, especially MRSA and MRSE. The published role of linezolid remains anecdotal (Bassetti et al. 2001).

In addition to these drugs, there is a substantial body of evidence supporting the use of ciprofloxacin. This has proved extremely useful for the treatment of gram-negative osteomyelitis (Lew and Waldvogel 1995). It has also assumed a role, in combination with rifampin, in the treatment of gram-positive infections where biofilms are believed to be an important element of the pathophysiology. The use dates from animal models of device-related infection in which cure of staphylococcal infection was observed with fluroquinolone-rifampin combinations. This led to observational studies in orthopedic device-related infection (Widmer et al. 1992; Drancourt et al. 1993), culminating in a randomized controlled trial of ciprofloxacin-rifampin therapy compared to ciprofloxacin monotherapy in patients with staphylococcal infection and a mechanically stable implant, who underwent prompt surgical debridement with retention of the implant (Zimmerli et al. 1998). The results clearly showed the ability of the combined regimen to cure infection with 3–6 months of therapy in selected cases. All the failures were seen in the monotherapy group, with the evolution of resistance in the same bacterial strain, as demonstrated by pulse-field gel analysis of the initial and relapsing isolates. It remains to be seen in larger series of orthopedic device-related infection how generalizable these findings will prove. Applying the same reasoning to chronic osteomyelitis, quinolone–rifampin combinations have also been used in this condition, particularly in diabetic foot osteomyelitis (Senneville et al. 2001). In this condition, several separate studies have shown that antibiotic therapy alone frequently suffices to treat osteomyelitis, though the lack of standardized definitions does cause some difficulty (Venkatesan et al. 1997; Pittet et al. 1999)

Topical

The need for surgical dead space management has already been discussed. A logical extension of this requirement, and arising from a view that if high doses of antibiotics are required these are best provided locally, is the incorporation of antibiotics into a suitable carrier that can be implanted at the site of infection. An ideal carrier would release high levels of active drug for a prolonged period, without generating high systemic levels of the drug. It would not in its own right be systemically or locally toxic, and would be absorbable and support or stimulate the production of new bone. The carrier would be compatible either with one or two agents that singly, or in combination, produce a very broad-spectrum regimen, or with a range of drugs that could be mixed in at the time of application, based on prior microbiological information (Wininger and Fass 1996). In practice, no carriers yet fulfill all these requirements. The most widely used system is polymethylmethacrylate (PMMA) bone cement, which can be loaded with a range of antibiotics (Figure 5). These include cefuroxime, gentamicin, amikacin, tobramycin, clindamycin, and vancomycin. Of these, gentamicin was first developed commercially (in Europe) and can be obtained as a mix for reconstitution, or precast into beads of varying sizes threaded into chains on wire (Wininger and Fass 1996; Walenkamp et al. 1998; Klemm 2001). Antibiotic loaded cements are not available pre-mixed in the USA for regulatory reasons, so surgeons who make use of them there have to hand mix antibiotic powder into standard cement, a procedure that can obviously lead to variations in the properties of the cement and the elution of the drug.

There are extensive data on the elution properties of gentamicin and to a lesser extent other antibiotics from PMMA cement, which indicate that very high local levels of drug are maintained in the immediate environment of the cement and in wound drainage fluid. These are maintained for upwards of two weeks before levels start to fall. Levels are so high that bacteria that are antibiotic resistant may nonetheless be killed. Elution of

Figure 5 *Post-operative radiograph, showing bone loss subsequent to debridement via a cortical bone window, and antibiotic loaded PMMA beads to manage the dead space*

antibiotic is from the exposed surface of the cement, with little drug diffusing out from the depths of the bead or block. This has implications for removal of spacers, which may potentially release bactericidal levels of drug if cracked or otherwise damaged (when new surfaces are exposed), affecting culture results.

In addition to its temporary use in spacers and beads, antibiotic loaded cement has also been used in revision of prosthetic joints. This may be in one- or two-stage exchange, or in rigid or articulating spacers. The latter are designed to preserve some joint movement, in the belief that morbidity is reduced, technical difficulties at reimplantation ameliorated and ultimate range of movement improved (Fehring et al. 2000; Emerson et al. 2002). There are even kits available with molds and internal metal scaffolds around which antibiotic loaded cement can be cast to give a relatively functioning, cement-surfaced implant, the PROSTALAC (prosthesis of antibiotic loaded acrylic cement) (Masri et al. 1994; Haddad et al. 2000; Meek et al. 2003). These may prove invaluable in managing major proximal femoral loss, by preserving function, muscle bulk, and an anatomic space for eventual implantation of a large definitive prosthesis. There are no controlled data on the use of functional spacers compared to static alternatives.

Alternatives to the use of PMMA cement as an antibiotic carrier are available. Gentamicin can also be incorporated into collagen fleeces, which can be packed into cavities and which should, over time, be absorbed (Kollenberg 1998). The kinetics of release differ from antibiotic-loaded PMMA cement, with high levels of antibiotic eluting over a much shorter period of time. Hydroxyapatite can be used (Yamashita et al. 1998; Shirtliff et al. 2002), and 'low technology' versions also exist, in the form of calcium phosphate (plaster of Paris) (Alonge et al. 2002; Santschi and McGarvey 2003), which can be reconstituted, with antibiotics incorporated, into sterile pellets for packing into bone defects (Benoit et al. 1997). This may be particularly valuable in parts of the world where resources are scarce (Alonge et al. 2002; Heybeli et al. 2003). Pellets have also been studied in the treatment of bony defects produced after debridement of diabetic foot ostomyelitis (Roeder et al. 2000).

The evidence base for the use of antibiotic-impregnated PMMA cement is relatively poor, but surprisingly, little different from that supporting the use of systemic therapies. An attempt at a randomized trial of gentamicin-loaded PMMA beads compared to systemic therapy was unsuccessful due to substantial protocol violations and concerns about the randomization (Blaha et al. 1993). Another study was abandoned when nursing staff refused to continue the traditional suction drainage approach in favor of the much simpler management of antibiotic-loaded PMMA beads (Walenkamp et al. 1998). Although systemic and local therapies have therefore never been adequately compared, nor have intravenous and oral therapies except in small studies.

One final concern in the use of antibiotic-loaded cement is the potential for persistence of the infection around the new foreign body. This certainly can occur if the pathogen has absolute resistance to the antibiotic in use (even at the very high doses released) but there is also the potential that small colony variants could be induced by the antibiotic and then persist. Clearly, for this mechanism to be plausible, residual infection would have to be present at the point the beads were used, which would be a risk factor for recurrence anyway. Nonetheless, small colony variants have been recovered from relapsed osteomyelitis in which antibiotic-loaded beads had previously been used (von Eiff et al. 1997).

Duration of treatment

The duration of treatment required varies according to the severity of the disease at the beginning of treatment, a concept that for chronic osteomyelitis at least, includes some sense of the local and systemic host factors that contribute to outcome. Taking this into account, the overall trend of treatment has, in general, been to reserve very prolonged treatment for situations where tissue that is dead or otherwise inanimate is retained in the infected field, and/or where the host has major systemic compromise. Where surgical resection produces remaining tissues that are minimally contaminated and viable, antibiotic treatment durations are reducing. In acute osteomyelitis, overall durations of therapy for uncomplicated infection are also falling (Le Saux et al.

2002; Vinod et al. 2002), in some series to as little as two weeks. Suggestions are given in Table 3, but it must be stressed that these have not been determined by a large series of clinical trials.

Adjunctive treatment

A range of adjunctive treatments has been proposed, the most common one being hyperbaric oxygen (Mader et al. 1990; Stone and Cianci 1997; Bakker 2000; Wunderlich et al. 2000; Wang 1997). This has its strong advocates, and there is laboratory evidence to suggest enhanced bacterial killing with hyperbaric oxygen. It is also believed to support increased function of phagocytes. Despite the existence of these data, the role of hyperbaric oxygen in the patient who has had debridement surgery and antibiotics is unclear. Randomized controlled trials will be crucial in allowing an informed view of the role of this treatment to emerge.

Other commonly advocated adjunctive treatments include Manuka honey, which is believed to have broad antimicrobial activity, and Tea Tree Oil. There is little available information on the value of these agents.

A final modality worthy of consideration is the use of maggots (larvae of the greenbottle fly, *Lucilia serricata*). The larvae of this species eat only dead tissue, and can be reared from eggs on chemically defined, sterile media; furthermore, the eggs themselves are highly resistant to external agents and so can be sterilized of microbiological contamination (Jukema et al. 2002). Larvae reared in this way are thus effectively sterile at the point of application to a wound, and are capable of carrying out efficient debridement. Some believe they also stimulate the formation of healthy granulation tissue. The use of maggots of this sort for the treatment of osteomyelitis was first put forward in the pre-antibiotic era, as an adjunct to sequestrectomy. Their role without surgery, and the extent to which they are necessary in the era of antibiotics and modern plastic surgical methods, is not defined; they certainly have proponents in the diabetic foot world and may be of value in situations where conventional surgery is deemed to carry too high a risk. Microbiologically, maggots develop a bowel flora that includes *Proteus* spp., and it must be assumed that the wound will be contaminated with this. Certainly the maggot secretions and excreta can be highly irritant to skin surrounding the wound, which itself becomes very exudative, and measures must be taken not only to contain the maggots (for obvious therapeutic and aesthetic reasons) but also to manage these wound secretions. In addition, maggots can carry a range of serious pathogenic *Clostridium* spp. in their gut; there were historical accounts of tetanus, botulism, and gas gangrene secondary to maggot use before the need for absolute sterility from egg onwards was identified. Much more recently, outbreaks of septicemia have been associated with the use of other species of maggot, stressing the need for this form of treatment to be subject to careful design and quality control. As with so much else in the management of osteomyelitis, randomized controlled studies are lacking. Even if maggots are effective in the management of diffusely necrotic soft tissue, their role in removing dead bone is open to question; this function is likely to require human intervention in most cases.

PROGNOSIS

The prognosis for acute infections is excellent provided the diagnosis is made promptly and the treatment is appropriate. Cure rates are over 95 percent in modern series of acute childhood hematogenous osteomyelitis. Function is generally good on treatment of infection, but in childhood osteomyelitis, annual follow up is required to look for growth plate disturbance. Acute septic arthritis also carries a good prognosis, with poor outcomes highly associated with delay in diagnosis and treatment (Christiansen et al. 1999). Acute prosthetic joint infection similarly requires rapid intervention for optimal outcomes, with salvage rates from debridement and retention procedures that can reach 70 percent (Karchmer 1998). Certain organisms, for example *Staphylococcus aureus*, confer worse prognosis; this is also seen in prognosis following one-stage revision of prosthetic joints. In relation to cure of infection, suppression (retention of chronically infected joints with long-term antibiotics) fares worse than debridement and retention of acute infections (Deirmengian et al. 2003), which are themselves outperformed by one-, and finally, two-stage revision. These achieve cure rates of 80–95 percent when antibiotic loaded cement is used.

Chronic osteomyelitis has high recurrence rates unless radical excision of dead bone is combined with antibiotic treatment. Recurrence rates in expert series are as low as 10 percent. Diabetic foot osteomyelitis has a poorer outlook, and responds to treatment in only 60–70 percent of cases (Grayson et al. 1994; Venkatesan et al. 1997; Pittet et al. 1999). This is due to the very much less favorable host factors operating, notably degrees of ischemia, and the relatively muted responses well recognized in diabetics (Armstrong et al. 1996). As a result, treatment frequently culminates in minor or major amputation; this is in part due to failure to eliminate the bone infection, but in a substantial number of cases, amputation is precipitated by the soft tissue loss that led to the osteomyelitis. If not fully surgically resected, osteomyelitis in many locations is well known to be able to recur decades after the initial event (Donati et al. 1999). There is no good evidence to suggest that the likelihood of this phenomenon is dictated by the initial treatment; the mechanisms of such prolonged dormancy remain unclear.

Table 3 *Indications for surgery and suggested duration of treatment*

Condition	Indications for surgery	Host biology after any surgery	Duration
Acute septic arthritis	Hip, shoulder, and when antibiotics alone fail. Arthroscopic washout now common	Normal	2 weeks for streptococci, *Neisseria* spp., *Haemophilus* spp.; 3 weeks for *Staphylococcus aureus* and gram-negative rods
		Arthritic joint, exposed bone or devitalized fibro-cartilage	4–6 weeks
Chronic septic arthritis	May need resection and fusion/arthroplasty if joint destroyed	Generally abnormal joint surface, exposed bone, and debris	As chronic osteomyelitis for pyogenic bacteria; *Brucella* spp. 3 months; *Mycobacterium* spp. as for osteomyelitis
Acute prosthetic joint infection	Mandatory, to establish diagnosis, microbiology, debride infected tissue, provide soft tissue cover. Remove implant if loose	Implant removed	6 weeks
		Implant retained	6 months–2 years (varying practice, lifelong treatment sometimes given)
Chronic prosthetic joint infection	Loose implant; pain; sinus or abscess formation	Implant removed definitively	6 weeks
		Implant revised in one stage	3–6 months
		Implant revised in two stages	6–12 weeks
		Implant retained	Indefinite
Acute osteomyelitis	Abscess formation	Infected but viable bone, no abscess	2–4 weeks
		Complicated (surgery required, dead bone)	4–12 weeks
Chronic osteomyelitis: long bone and foot	Dead bone; loss of soft tissue cover; abscess; pain; multiple acute flares	The whole of the involved bone removed (ablative treatment, e.g. amputation), with normal remaining soft tissue	1–3 days
		The whole of the involved bone removed, but with residual soft tissue infection	1–2 weeks
		All dead bone removed, but viable portion of infected bone remains	4–6 weeks
		Residual dead bone currently or previously involved in infected field	12 weeks or more
Chronic osteomyelitis: spine	Abscess; spinal instability; pain; progressive deformity; spinal cord compression	No metal ware	6–12 weeks
		Retained metal in infected field	3–12 months

FUTURE DIRECTIONS

The area of musculoskeletal infection still needs definitive answers to questions such as how best to diagnose and treat infection in the most cost-effective way. The necessary duration, and the favored route of administration (if one exists) are yet to be determined, as is the difference in outcome and morbidity between one- and two-stage revision for prosthetic joint infection. Prediction of successful cure with medical therapy alone remains difficult, and there is yet to be a significant translation into clinical practice of recent advances in understanding the mechanisms of bone loss and bacterial pathogenesis.

CONCLUSIONS

Bacterial infections of bone and joint continue to pose major challenges and questions, which understandings of pathogenesis, diagnosis, and treatment options go only some way to answering. It is to be hoped that improved multidisciplinary working will increase clinical confidence in the management of these problems, and pave the way for the definitive studies that are required to establish a strong evidence base available to all.

Conventional laboratory diagnosis of infection

JOSEPH D.C. YAO

Introduction	1	Diagnostic methods	2
Clinical specimens	1	References	10

INTRODUCTION

Diagnosis of a microbial infection usually begins with an assessment of the clinical and epidemiologic features, leading to formation of a diagnostic hypothesis. Physical and radiological findings provide clues in determining the anatomic site of infection. This clinical diagnosis suggests a number of possible etiologic agents causing the infection, based on knowledge of infectious syndromes and their usual clinical courses. By applying various diagnostic microbiologic tests on clinical specimens, a specific microbial etiology can be established. Therefore, clear communication between the clinician and the clinical microbiology laboratory is essential to obtain optimal test results for arriving at an accurate microbiologic diagnosis. The clinician must select the appropriate tests and specimens to be processed and suggest the suspected microbial pathogens to the laboratory. The clinical microbiology laboratory must utilize a series of tests that would demonstrate the probable etiologic agents and be prepared to explore other possible agents suggested by the clinical features or findings of the laboratory examinations.

This chapter provides an overview of the appropriate use of the clinical microbiology laboratory and the various common conventional laboratory methods used for establishing the microbial causes of infection. Molecular laboratory methods are discussed separately in Molecular laboratory diagnosis of infection,
while additional specialized tests for identifying specific pathogens are described in the chapters devoted to specific microorganisms. Detailed descriptions of the principles and techniques of these diagnostic laboratory methods are available in several standard textbooks on this subject (Forbes et al. 2002; Murray et al. 2002).

CLINICAL SPECIMENS

Because the objective of most microbiologic laboratory tests is to isolate viable organisms, proper specimens must be collected and delivered promptly in a suitable transport system for processing in the laboratory. The results of these laboratory tests are limited by the quality of specimens and their condition on arrival in the laboratory. Errors in specimen collection and transportation are the most common reasons for failure to ascertain etiologic diagnoses of infections. Therefore, proper collection and transport of clinical specimens from the patient's bedside to the laboratory are the critical first steps in establishing a microbiologic diagnosis.

Collection

Specimens should be obtained from the patient with care to minimize the possibility of introducing extraneous or contaminating microorganisms that are not involved in the infectious process. This precaution is needed especially to distinguish resident (commensal) or 'normal' organisms from those causing the infection. The presence of commensal or normal flora at the anatomic site of infection will mask the true etiological agent, making its isolation more difficult. Of particular

Table 1 *Sites of infection and common sources of contamination*

Site of infection	Source of contamination
Middle ear	External ear canal
Nasal sinus	Nasopharynx
Lower respiratory tract	Oropharynx
Endometrium	Vagina
Superficial wounds/ subcutaneous infections	Skin and mucous membranes
Abdominal fistulae	Gastrointestinal tract
Bladder	Urethra and external genitalia

difficulty are specimens from sites listed in Table 1, which are adjacent to body sites having more resident flora than others. For example, expectorated sputum specimens are frequently contaminated during collection by organisms that are part of the indigenous or normal flora of the oropharynx. Knowledge of the potential contaminating organisms and the probable pathogens to be sought in these 'indirect' specimens is essential to avoid misinterpretation of results. Guidelines to assess the quality of such 'indirect' specimens have been developed to determine the suitability of a specimen for processing. Such an example is the use of microscopic examination of direct Gram-stained smear of expectorated sputum to indicate the high probability of contaminating flora when >10 squamous epithelial cells are present per low-power field (10× magnification).

Use of special techniques or procedures that bypass anatomic areas containing normal flora whenever feasible (e.g. protected brush bronchoscopy for diagnosis of ventilator-associated pneumonia) can prevent false-positive results. Careful skin antisepsis before collection procedures, such as blood cultures and lumbar punctures, will decrease the risk of false-positive findings from contamination by organisms normally present on the skin. Whenever possible, specimens should be collected directly from normally sterile tissues (e.g. lung, liver, bone marrow) and body fluids (e.g. blood, CSF, synovial fluid) by methods ranging from needle biopsy or aspiration to surgical biopsy. Positive findings obtained from these specimens are almost always diagnostic.

Though convenient and most commonly used for specimen collection, the sterile swab absorbs a small volume of specimen material and provides the poorest conditions for microbial survival. If available, infected tissue or needle aspirates of infected fluid should be submitted for microbiologic cultures. An adequate volume of specimen is important for optimal test results because infecting organisms present in small quantities may not be detected in a small sample. Specimens should be collected during the early (acute) phase of an infection and before initiation of antimicrobial therapy, whenever possible.

Transport and handling

Ideally, specimens should be transported to the laboratory as soon as possible, preferably within 30 min of collection. Some microorganisms can only survive briefly outside the body (e.g. *N. gonorrhoeae*) and are susceptible to environmental conditions, such as presence of oxygen (anaerobic bacteria), changes in temperature (*N. meningitidis*), or changes in pH (*Shigella*). To minimize the effects of delay between specimen collection and laboratory processing, various transport media have been developed for specimens that could not reach the laboratory in less than 30 min. These media are usually buffered fluids or semisolid media that contain minimal nutrients and special preservatives to prevent drying, maintain a neutral pH, and minimize bacterial growth during transport. Specialized media providing oxygen-free atmosphere are needed for transporting obligate anaerobes. Detailed comprehensive lists of optimal specimen selection and transport requirements are available in several authoritative references (Miller et al. 2003; Murray 1998).

When received in the laboratory, clinical specimens are processed with priority given to those that are most critical, such as blood, cerebrospinal fluid (CSF), sterile body fluids, and tissue. After macroscopic examination of each specimen to ensure appropriateness and adequate volume for the tests requested, some specimens may need to undergo initial processing by procedures before inoculation on to culture media. These procedures include homogenization (grinding) of tissue, concentration by centrifugation or filtration of large volumes of sterile fluids (ascites, pleural fluid), or decontamination to remove commensal flora that may interfere with recovery of fastidious pathogenic microbes (e.g. mycobacteria, *Legionella*).

DIAGNOSTIC METHODS

The general approaches to laboratory diagnosis of infectious diseases vary with different infective pathogens and infections. The types of conventional diagnostic methods employed for testing clinical specimens are usually a combination of direct examination, culture, microbial antigen detection, and detection of patient's antibody response (serology). In recent years, molecular laboratory methods (see Molecular laboratory diagnosis of infection) capable of directly detecting microbial genomic components have gained increasing importance and popularity for the sensitive and rapid detection of fastidious pathogens that are otherwise difficult to detect by conventional approaches.

Direct examination

Other than some of the parasites, none of the microbial pathogens present in clinical specimens are large enough

Table 2 *Utility of microscopic methods for diagnostic microbiology*

Microscopic methods	Bacteria	Fungi	Viruses	Parasites
Bright-field (light) microscopy	+	+	−	+
Dark-field microscopy	±	−	−	−
Phase-contrast microscopy	−	±	−	±
Fluorescent microscopy	+	+	+	+
Electron microscopy	−	−	±	±

+, commonly used; ±, limited use; −, rarely used.

to be visible with the naked eye. Therefore, microscopic examination of clinical specimens is necessary for the initial detection and preliminary or definitive identification of bacterial cells in infected cells. In diagnostic microbiology, five microscopic methods are used with varying utility for each of the four major microbial pathogen groups (Table 2). To better visualize and differentiate these microbes in smears of clinical specimens and histologic sections of tissues, various stains are used commonly in the diagnostic laboratory. As shown in Table 3, these staining techniques are adapted for specific microscopic methods in detecting and identifying certain microorganisms.

LIGHT MICROSCOPY

Direct examination of unstained or stained preparation of clinical specimens by bright-field (light) microscopy is used commonly for detection of bacteria, fungi, and parasites. Due to the minute sizes of bacteria (usually 0.3–0.5 μm wide), oil immersion magnification (500× to 1 000×) is necessary to visualize these organisms. Unstained bacteria are too transparent to be seen directly, but two important staining methods, Gram stain and acid-fast stains, are frequently employed to stain and classify bacteria by light microscopy.

Gram stain

As the principal stain used for microscopic examination of bacteria, the Gram stain divides most bacteria into two groups: gram-positive (purple-colored) when the alkaline dye, crystal violet, is retained by the organism, and gram-negative (pink-colored) when the crystal violet dye is lost with uptake of counterstaining safranin dye. Due to abundant peptidoglycan and teichoic acid cross-linkages in their cell wall, gram-positive bacteria are able to retain the crystal violet dye which is chemically bonded to the Gram's iodine reagent, while resisting alcohol or acetone decolorization in the subsequent

Table 3 *Microscopic preparations and staining methods commonly used for examination of clinical specimens in diagnostic microbiology*

Staining method	Detectable microorganisms
Direct examination	
Wet mount	Parasites and ova (examined by bright-field, dark-field, or phase-contrast microscopy)
10% KOH	Fungal hyphae
Lugol's iodine	*Entamoeba*, other amoeba
Differential stains	
Gram stain	Bacteria, yeast cells
Iron hematoxylin stain	Fecal protozoa
Toluidine blue O stain	*Pneumocystis jiroveci*
Trichrome stain	Fecal protozoa
Wright–Giemsa stain	Blood parasites (filaria, *Plasmodium*, *Babesia*), *Borrelia*, *Rickettsia*, *Ehrlichia*, *Anaplasma*, *Toxoplasma*, *Leishmania*, *Pneumocystis*, viral and chlamydial inclusion bodies
Acid-fast stains	
Ziehl–Neelsen stain	*Mycobacterium* spp.
Kinyoun stain	*Mycobacterium* spp.
Modified acid-fast stain	*Nocardia*, *Rhodococcus*, *Gordonia*, *Tsukamurella*, *Cryptosporidium*, *Isospora*, *Sarcocystis*, *Cyclospora*
Fluorescent stains	
Acridine orange stain	Bacteria cells, fungi elements
Auramine-rhodamine stain	*Mycobacterium* spp.
Calcofluor white stain	Fungal elements, *Pneumocystis*
Direct fluorescent antibody stain	*Chlamydia*, *Bordetella*, *Francisella*, *Legionella*, *Neisseria*, *S. pyogenes*, *Cryptosporidium*, *Giardia*, RSV, influenza virus, HSV, VZV

Adapted from Murray et al. (2002).

staining procedure. Gram-negative bacteria, having a thinner cell wall layer of peptidoglycan, lose the crystal violet dye easily during the decolorization process and appear pink in color from uptake of the safranin counterstain dye. Gram-positive bacteria without an intact cell wall because of cell damage, old age, or antibiotic therapy, may fail to retain the crystal violet dye during decolorization and appear 'gram-variable,' with a mixture of purple- and pink-staining cells.

Acid-fast stain

The acid-fast stain is used specifically for direct light microscopic detection of mycobacteria and related bacteria in clinical specimens. The presence of mycolic acids in their cell wall renders this group of bacteria 'acid-fast' (resistant to acid alcohol decolorization) and difficult to stain with dyes, including Gram stain. However, they can be stained by prolonged application of highly concentrated dyes, with or without the use of heat treatment to facilitate the staining process. Once stained, acid-fast bacteria resist acid alcohol decolorization which removes the same dyes from other bacteria. Ziehl–Neelsen stain is the classic acid-fast stain with heated carbol-fuchsin (red) applied as the primary stain, followed by decolorization with 3 percent HCl–alcohol and counterstaining. A modified method, also known as the Kinyoun acid-fast stain, involves using carbol-fuchsin containing a higher concentration of phenol to facilitate penetration of the primary dye without use of heat.

DARK-FIELD MICROSCOPY

Using special optical features of dark-field microscopy, bacteria that are usually too thin to be visualized by light microscopy can be seen as objects surrounded by a bright halo amid a dark background. This method is used to detect spirochetes, such as *Treponema pallidum* (syphilis) and *Borrelia* spp. in clinical specimens.

PHASE-CONTRAST MICROSCOPY

Phase-contrast is an optical technique that yields visible contrast among microbial cells and cell structures in a given specimen. Objects with different thickness or densities have different refractive indices that produce different light intensities (phases) in an image, allowing better visualization of cell structures in unstained specimens. Whereas microscopic examination of stained specimens permits observation of dead organisms, phase-contrast microscopy offers the advantage of observing viable organisms of interest. This method is used mainly for the identification of fungi and parasites.

FLUORESCENT MICROSCOPY

Using similar optical features as dark-field microscopy, fluorescent microscopy is used to detect microorganisms that are labeled by a fluorescent dye (e.g. acridine orange, calcofluor white, auramine-rhodamine) or by microbial antigen-specific antibody conjugated with a fluorescent dye (immunofluorescence). Against a dark background, the organism of interest appears with a halo emitting color of the fluorescent compound. This method is used to detect organisms that are difficult or slow to grow or to identify those already grown in culture.

ELECTRON MICROSCOPY

With its high magnification of $\geqslant 100\,000\times$, electron microscopy is used mainly for the detection and identification of viruses in clinical specimens and viral cultures. It is also a useful method for the confirmation of microsporidia (e.g. *Enterocytozoon*, *Encephalitozoon*) in clinical specimens. However, the need for specialized equipment limits the availability of this method for routine use in diagnostic microbiology.

Isolation and identification

The most definitive and specific means of diagnosis of an infection is the isolation and identification of the infecting organism in vitro from clinical specimens. To identify and characterize the organism, it must be grown and isolated in the clinical laboratory. Although most bacteria can be cultivated by various artificial media, strict intracellular organisms such as *Chlamydia*, *Rickettsia*, and *Ehrlichia* can be isolated only from cultures of living eukaryotic cells (cell cultures).

Cultivation of bacteria in the laboratory involves inoculating clinical specimens obtained from the infection site into culture media and growing the microorganisms of interest in vitro. Once they are grown in culture, the organisms are present in sufficient amounts to allow further diagnostic laboratory testing to be carried out. Their survival depends on the availability of essential nutrients and appropriate environmental conditions in vitro. The nutritional needs include different gases, water, ions, sources of carbon and nitrogen, and energy. For certain bacteria, the needs are complex, so that exceptional nutrient components must be added in the culture media to support their growth. Pathogens with such growth requirements are said to be fastidious. To date, the growth requirements of certain clinically relevant bacteria, such as *T. pallidum* and *M. leprae*, remain poorly understood such that these pathogens cannot be grown in vitro.

BACTERIOLOGIC CULTURE

Various artificial culture media are employed in the diagnostic laboratory to facilitate the growth of medically important bacteria to be detectable by the naked eye. These media are essentially recipes prepared from digests of animal or plant protein supplemented with nutrients such as glucose, yeast extract, serum, or blood, to meet the metabolic requirements of the organisms (Atlas 1997; Chapin and Lauderdale 2003; Chapin and

Murray 2003). Bacteriologic media can be prepared in solid (agar), semisolid, and liquid (broth) forms to which bacteria or clinical specimens may be added directly. On solid agar plates, bacteria grow as discrete sediment (colonies) or as a film on the agar surface, while their growth is not visible in semisolid and broth media until there are 10^6 to 10^7 bacteria per milliliter of media to produce turbidity or macroscopic clumps.

Compared to broth cultures, solid media offer advantages for diagnostic work, since discrete colonies of bacteria in pure culture grow well separated from one another on the agar surface and arise from a single organism or an organism cluster (colony-forming unit). Bacterial colonies differ significantly among different genera or species, varying greatly in size, shape, color, texture, and other characteristics. For example, colonies of *S. pneumoniae* possessing large polysaccharide capsules are usually mucoid in appearance, while those of organisms that fail to separate after division are frequently granular. These features are usually consistent for colonies derived from the same strain of organism. Therefore, differences in colonial morphology are very useful as clues to bacterial identity and for separating them in mixtures. Broth media offer the advantage of providing a favorable homogeneous environment for enhancing bacterial growth in recovering organisms that are present in minute quantities in clinical specimens. However, broth cultures of clinical specimens frequently yield mixtures of bacteria that are not readily separated for identification.

Bacteriology media may be classified as nutrient, enrichment, selective, or differential media according to their main function in the laboratory. Nutrient media, also known as supportive media, are designed to provide the growth requirements of most nonfastidious bacteria without giving growth advantage to any particular organism. Mueller–Hinton medium and brain–heart infusion in agar or broth are such examples. Enrichment media contain specific nutrients (e.g. trace metals, coenzymes, vitamins) necessary for the growth of certain bacteria. They are used to enhance the growth of a particular bacterial pathogen from a mixture of organisms on the basis of nutrient specificity. Typical examples are thioglycolate broth, chocolate agar (*Neisseria* and *Haemophilus* species), and buffered charcoal-yeast extract agar (*Legionella* spp.). Selective media contain dyes, bile salts, acids, alcohols, or antimicrobial agents that are inhibitory to all organisms except those being sought. Selecting for the growth of certain bacteria to the disadvantage of others, these media are useful for isolating specific pathogenic organisms from clinical specimens containing extensive contaminating flora. *Campylobacter*–blood agar, mannitol salt agar or broth (staphylococci), and phenylethyl alcohol agar (gram-positive cocci) are commonly used selective media. Differential media contain substances that allow colonies of specific pathogens or organism groups to exhibit certain biochemical or other culture characteristics distinguishable from other organisms growing in the same media. Such culture features may be based on changes in pH as a result of carbohydrate metabolism, enhancement of pigment production, or hemolysis of red blood cells present in the media. Examples of such media are bile esculin agar (enterococci), MacConkey sorbitol agar (*E. coli* O157:H7), and sheep blood agar (streptococci). Some media have multiple functions, such as enriched and selective (Thayer–Martin agar for *N. gonorrhoeae* and *N. meningitidis*, Columbia colistin-nalidixic acid with 5 percent blood for gram-positive cocci), enriched and differential (sheep blood agar for hemolytic streptococci), selective and differential (eosin methylene blue agar and MacConkey agar for gram-negative bacilli, Hektoen enteric agar for *Salmonella* and *Shigella* spp., thiosulfate citrate-bile salts agar for *Vibrios* spp.).

BACTERIAL IDENTIFICATION

In addition to Gram-stained smears, conventional methods of bacterial identification involve examination of the cultural characteristics, as well as biochemical and physiologic testing on pure cultures obtained from single colonies. The exact tests and the sequence of testing depend on the suspected group of bacteria and the taxonomic level of identification (e.g. genus, species, subspecies) needed for diagnosis and treatment of the infection. Important properties of bacterial cultures that aid in identification include unique nutritional requirements, pigment production, and the ability to grow in the presence of certain substances (e.g. bile, sodium chloride) or on certain selective or differential media (e.g. MacConkey agar, Hektoen enteric agar), growth at particular temperature, and presence and type of hemolysis (alpha, beta, gamma) on blood agar.

The ability to react with certain chemical substrates and the production of particular metabolites form the basis of biochemical tests for bacterial identification. Such tests include utilization of carbohydrates (e.g. sucrose, glucose, lactose) and citrate, ability to metabolize certain amino acids (e.g. lysine, ornithine, arginine), oxidase reaction, and production of catalase, coagulase, proteinase, urease, indole, and hydrogen sulfide (Chapin and Lauderdale 2003). The results of these tests are analyzed by reference to published algorithms for identification of many bacteria (Ruoff 2003; Funke 2003; Schreckenberger and Wong 2003; Citron 2003; Versalovic 2003).

Bacteria may also be identified by the presence of their antigenic structures, such as capsular polysaccharides, flagellar proteins, and cell wall components. In addition, in vitro detection of specific bacterial toxins, with neutralization of the toxic effect by specific antitoxin, may be necessary to confirm the identity of pathogenic bacteria (e.g. Elek immunodiffusion test for

Corynebacterium diphtheriae toxin) or a clinical diagnosis (e.g. *Clostridium difficile* toxin). Serologic techniques using bacteria-specific antibodies can detect these antigens present on whole bacteria or free in bacterial lysates (soluble antigens). Further details of these methods are discussed in a later section.

Blood cultures

The primary means for establishing diagnosis of bloodstream infections due to bacteria and fungi is by blood culture, which is based on the same microbiologic principles of any culture. A sample of patient's blood is obtained by aseptic venipuncture and inoculated into an enriched broth or agar plate. Once growth is detected by manual or automated methods, the organisms are isolated, identified, and tested for antimicrobial susceptibility. Careful attention must be paid to details of obtaining blood from the patient in order to maximize the yield of blood culture and properly interpret the results.

Proper antiseptic techniques should be used to prepare the skin over the vein for phlebotomy, so that contamination of the blood culture by skin microbial flora is minimized. Blood should not be drawn through indwelling venous or arterial catheters unless it cannot be obtained by venipuncture, or if it is for detection of intravascular catheter-associated sepsis. Many commercially available blood culture media contain an anticoagulant, sodium polyanethol sulfonate (SPS), which is free of antimicrobial properties and has anticomplementary and antiphagocytic activities. SPS also interferes with the activity of some antibiotics, notably aminoglycosides, that are present in the blood of patients receiving antibiotic therapy. Blood cultures obtained from patients after initiation of antimicrobial therapy are not useful unless none was collected before starting therapy or the clinical course of the infection suggests superinfection with a drug-resistant or other microorganism.

Since the number of organisms present in blood is often low (<10 organisms/ml), the yield of blood cultures in a given patient is also dependent on the amount of blood and the number of blood cultures obtained. The diagnostic yield increases as the blood volume drawn is increased. Collection of a minimum 5–10 and 20 ml of blood per culture is strongly recommended for pediatric and adult patients, respectively. Because microorganisms causing infection may enter the blood continuously, intermittently, or transiently, blood infections may not be detectable by a single blood culture. If the blood volume drawn per culture is adequate, two or three blood cultures collected at brief intervals (30–60 min apart) are usually sufficient to yield positive results.

Most diagnostic laboratories currently utilize automated blood culture systems, such as BacT/ALERT® 3D System (bioMerieux, Durham, NC, USA), Bactec™ 9000 Systems (Becton Dickinson Diagnostic Systems, Sparks, MD, USA), and ESP® Culture System II (TREK Diagnostic Systems, Cleveland, OH, USA), for consistent quality control and optimal work efficiency. However, some pathogens, especially intracellular microorganisms such as *Histoplasma*, *Legionella*, and *Mycobacterium* spp., are not easily recovered by these automated culture systems. The lysis centrifugation blood culture method (e.g. ISOLATOR™ Microbial Tubes; Wampole Laboratories, Cranbury, NJ, USA) would be helpful for detection of bloodstream infections due to these pathogens. The ISOLATOR™ tubes contain SPS and saponin which causes lysis of blood cells, releasing intracellular pathogens into the blood. After centrifugation, the supernatant is discarded and the sediment containing the pathogens is inoculated on to solid agar plates capable of supporting the growth of the pathogens of interest. This manual blood culture method provides the following benefits: more rapid and greater recovery of the pathogens, presence of colonies for direct identification and susceptibility testing after initial incubation, and ability to quantify the number of colony-forming units present in the blood.

Results of blood cultures yielding growth of coagulase-negative staphylococci, *Corynebacterium* spp., *Propionibacterium acnes*, *Bacillus* spp. should be interpreted with caution because these organisms are part of the normal skin flora and are frequent contaminants in blood cultures. Growth of multiple species from only one of several cultures would also suggest probable contaminants, since polymicrobial bloodstream infections are uncommon. When the same isolate is recovered from multiple blood cultures obtained at different times or from different anatomic sites, bloodstream infection from this organism is probably real.

Blood cultures obtained for the diagnosis of infections due to fastidious pathogens require special processing in the laboratory, so that special procedures or culture media are used to support the growth of these organisms. Routine automated blood cultures are unlikely to recover such pathogens as *Brucella*, *Borrelia*, *Leptospira*, *Bartonella*, *Mycoplasma hominis*, *Legionella*, *Mycobacterium* spp., and the HACEK group of fastidious gram-negative bacilli. The laboratory should be alerted to process the blood cultures accordingly when one of these pathogens is suspected to cause bloodstream infection in a given patient.

Antimicrobial susceptibility testing

In vitro susceptibility testing of microbial pathogens to antimicrobial agents is an important function of the clinical microbiology laboratory. Testing guidelines, standardized procedures, and interpretative criteria are regularly updated and available from the National Committee for Clinical Laboratory Standards (NCCLS)

in the USA (NCCLS, 2000, 2001, 2002a, b, 2003a, b, c, d, e) and from its counterparts in other countries (EUCAST 2000, 2003). The goal of susceptibility testing is to provide data on antimicrobial resistance in conjunction with other diagnostic information to optimize therapy. Of the methods available to detect and evaluate antimicrobial resistance in bacteria, the conventional methods of directly measuring the activity of the antibiotics against a given infecting isolate are the most widely employed by laboratories. These conventional testing methods include broth dilution, agar dilution, and disk diffusion.

The broth dilution susceptibility test consists of inhibiting the growth of the isolate of interest by a series of doubling broth dilutions (e.g. 0.25, 0.5, 1, 2, 4, 8, 16 μg/ml) of a given antibiotic. The concentration range tested for a particular drug depends on the following criteria: (1) the drug concentration that is safely achievable in a patient's serum (i.e. pharmacokinetic properties of the drug); and (2) the microorganism and its associated antimicrobial resistance features that the test is attempting to detect. The lowest antibiotic concentration that completely inhibits visible pathogen growth in the broth solution is known as the minimal inhibitory concentration (MIC). Broth dilution testing can be performed in two approaches with the same principles: macrodilution and microdilution. The macrodilution method involves testing the pathogen in test tubes containing antibiotic dilution in a broth volume of $\geqslant$1 ml per tube. This approach is cumbersome and labor intensive, and it is rarely used in clinical laboratories. For microdilution testing, the total broth volume is in the range of 0.05 to 0.1 ml for each antibiotic dilution. This method is usually adapted in a convenient, single microtiter tray format with multiple sample wells for several serial dilutions of various antibiotics. Several commercially available manual and automated susceptibility testing systems in use at many laboratories are developed according to this format: MicroScan® WalkAway System (Dade International, Sacramento, CA, USA), BD PHOENIX™ Automated Microbiology System (BD Diagnostic Systems, Sparks, MD, USA), Vitek® 2 System (bioMérieux, Inc., Durham, NC, USA), Sensitive® Microbiology Systems (TREK Diagnostic Systems Inc., Cleveland, OH, USA), and PASCO MIC Panels (PASCO Laboratories, Wheat Ridge, CO, USA).

In agar dilution susceptibility testing, each dilution of a given antibiotic is incorporated into a single agar plate, on which multiple isolates can be inoculated each at a standardized inoculum of 10^4 colony-forming units (cfu). A series of six dilutions of an antibiotic would require using six antibiotic-impregnated agar plates and one positive growth control plate without antibiotic, with $\geqslant$1 isolates tested per plate. After incubation, the plates are examined for growth, with the MIC being the lowest concentration of an antibiotic in agar that completely inhibits visible growth. The main advantage of this method is that MICs can be determined for fastidious organisms, such as *N. gonorrhoeae* and *E. corrodens*, that do not grow well in the broth media used in the broth dilution method. However, preparation of agar dilution plates is labor intensive, so this testing method is limited to use by reference laboratories testing large numbers of isolates daily.

The disk diffusion method is a practical and convenient approach of antimicrobial susceptibility testing, in which antibiotic-impregnated filter paper disks ('antibiotic disks') are placed on the surface of an agar plate that has been inoculated with a lawn of bacteria. Each antibiotic disk contains a known concentration of antibiotic, and the drug diffuses out of the disk into the surrounding agar, creating a concentration gradient around the disk. During incubation, the bacteria grow on the surface of the agar plate, except where the antibiotic concentration gradient is sufficiently high to inhibit growth. Findings of in vitro studies are used to correlate the size (in millimeters) of the resulting zone of inhibition around each disk with the MIC of the drug obtained by broth or agar dilution method.

A commercial susceptibility testing method that combines the convenience of disk diffusion with the ability to determine MIC data is the Etest® (AB Biodisk, Solna, Sweden). It is a unique patented antimicrobial gradient diffusion technique in which a predefined gradient of 15 dilutions of an antibiotic is impregnated on to a single plastic reagent strip. The strip is then placed on to the surface of an inoculated agar plate, allowing a gradient of antibiotic to diffuse from the strip into the surrounding agar. After incubation, the resulting elliptical zone of inhibition intersects the scale of antibiotic dilution markings at the indicated MIC on the strip. Reagent strips of various antibiotic agents are available for testing both fastidious and nonfastidious bacteria and *Candida* spp. The main disadvantage of this method is the relatively high cost of the reagent strips when several antibiotic strips are needed to test a given pathogen isolate.

To interpret test results reliably, antibacterial susceptibility testing methods are standardized and carefully controlled according to the appropriate inoculum size of the organism, conditions of growth medium (pH, calcium and magnesium cation concentrations, blood and serum supplements, thymidine content), incubation atmosphere, temperature and duration, and antibiotic concentrations tested (NCCLS 2003d). Procedural standards and interpretive guidelines have been published for the broth and agar dilution methods (NCCLS 2001, 2002a, b, 2003b) and the disk diffusion testing method (NCCLS 2003a, c). Use of the interpretive guidelines enables laboratories to report susceptibility test results on a pathogen as 'susceptible,' 'intermediate,' or 'resistant' to a given antibiotic. However, in some instances, the MIC value is more valuable in directing therapy than a simple qualitative result because the clinician can

determine the potential success or failure of antibiotic therapy when comparing the MIC to the antibiotic level achievable at the anatomic site of infection. Because no one method can provide adequate testing of all clinically important bacteria, most diagnostic laboratories usually employ a combination of the susceptibility testing methods described above.

Detection of microbial antigens

Immunologic techniques are frequently used to detect, identify, and quantitate antigens of microbes directly in clinical specimens or from microbiologic cultures. These techniques are based on binding interactions between antibody and specific antigen, forming antibody–antigen complexes that can be detected directly by precipitation methods or by labeling of the antibody with a radioactive, fluorescent, or enzyme probe. The complexes can also be detected indirectly by measurement of an antibody-directed reaction, such as complement fixation.

PRECIPITATION AND IMMUNODIFFUSION METHODS

The principle of these tests is based on the formation of precipitate from interaction between soluble antigen and antibody. The precipitate is visible only because the antigen–antibody complexes formed are too large to remain soluble and therefore precipitate. At antigen-to-antibody concentration ratios above and below an equivalence concentration, the complexes are soluble. Further details are described in the section on Serologic methods below.

Immunodiffusion (ID) assays are adaptations of the precipitation technique to determine the identity of an antigen or the presence of antibody. In single radial immunodiffusion tests, antigen is placed into a well and allowed to diffuse into surrounding agar containing a specific antibody. The higher the concentration of antigen, the farther it diffuses in the agar to reach equivalence with the antibody and forms a precipitate ring around the well.

AGGLUTINATION TESTS

When relatively large particles coated with antigen or antibody are allowed to react with the specimen of interest (e.g. serum, CSF, urine), the resulting antigen–antibody reactions are detectable visually by agglutination. Soluble antigen or antibody can be fixed on to the surface of red blood cells or microscopic latex particles, and the assays are known as passive hemagglutination and latex agglutination, respectively. Bacterial antigens present on surfaces of whole bacteria that are large enough to behave as particles may also agglutinate with bacteria-specific antibody (bacterial agglutination). These assays are rapid and technically simple tests for identification of bacteria isolated in pure cultures (e.g. coagglutination test for staphylococcal surface protein A) and for detecting microbial antigens directly in clinical specimens.

IMMUNOFLUORESCENCE ASSAYS

Antigens present on the cell surface or within the cell can be detected by direct or indirect immunofluorescence (IF). In direct IF, antibody to the specific antigen is bonded directly with a fluorescent molecule, usually fluorescein isothiocyanate (FITC), whereas in indirect IF, a second antibody specific for the primary antibody is labeled and used to detect the primary antimicrobial antibody and locate the antigen. Indirect IF assays are usually more sensitive than direct IF tests, but the latter are faster, involving only one incubation step. IF tests are used to identify *Bordetella pertussis* in culture and to detect *Legionella pneumophila* in clinical specimens.

ENZYME IMMUNOASSAYS

Enzyme immunoassays (EIA), also known as enzyme-linked immunosorbent assay (ELISA), utilize antibodies conjugated to enzymes (e.g. horseradish peroxidase, alkaline phosphatase) capable of catalyzing a reaction yielding a visible end product, while the antibody-binding sites remain free to react with their specific antigen. The advantages of such assays are: ability to amplify the antigen–antibody reaction and enhance the sensitivity of detection, relatively long-term stability of the enzyme-conjugated antibodies during storage, and formation of a colored end product that allows both visible detection or automated spectrophotometric measurement. The use of monoclonal antibodies also helps to increase the specificity of these assays. Examples of commercial EIA developed for the direct detection of bacteria in clinical specimens include *Streptococcus pyogenes*, *Streptococcus agalactiae*, *Helicobacter pylori*, and *Chlamydia trachomatis*.

Serologic methods

Immunocompetent humans produce both IgM and IgG antibodies against pathogens during infection. In general, IgM is produced during the first exposure to a given pathogen and is no longer detectable after this relatively short period of time. Over time, production of IgG replaces that of IgM in the immunologic response of the exposed patients. This humoral immune response in the infected hosts is the basis of serologic diagnosis of infection. Serologic testing is commonly used to identify infections due to bacteria that are difficult to be detected by other conventional methods, to evaluate the course of an infection, and to determine the nature of the infection (primary infection versus reinfection, acute versus chronic infection). Serologic results are usually expressed as a titer, which is the inverse of the greatest

dilution, or lowest concentration (e.g. dilution of 1:16 = titer of 16) of a patient's serum that retains the specific antibody–antigen reactivity. Patient's specific IgM or IgG titers can be determined separately through the use of labeled antihuman antibody specific for the antibody isotype in the particular serologic assays.

Serologic diagnosis of infection is confirmed usually by occurrence of seroconversion during a primary infection. Seroconversion is defined as a minimum four-fold increase in antibody titer between serum during the acute phase of infection and that during the convalescent phase ($\geqslant$2 weeks later). Reinfection or recurrent infection later in life causes an anamnestic (secondary or booster) immune response which can be detected as increase in antibody titer.

Most of the immunologic methods for detecting and identifying microbial antigens are also applied to serologic diagnosis by reversing the detection system: using a known antigen to detect the presence of the specific antibody. These serologic methods used in diagnostic laboratories include precipitation, immunodiffusion, agglutination, hemagglutination inhibition, EIA, indirect IF, complement fixation, radioimmunoassay, and Western blot. Some of these methods have been discussed in detail in the above sections.

PRECIPITIN TESTS

As described above, these tests are based on formation of a visible precipitate when antigen and antibody are combined in proper proportions. Two variations of the precipitin tests, flocculation and counterimmunoelectrophoresis (CIE), are available for serologic studies. In flocculation tests, the precipitin forms macroscopically and microscopically visible clumps. An example of such a test is the Venereal Disease Research Laboratory test (VDRL), in which the test antigen (cardiolipin–lecithin-coated cholesterol particles) binds to an antibody-like protein (reagin) in sera of patients with syphilis, causing flocculation of the particles. However, since reagin is not an antibody specific for *T. pallidum* antigens, the test is not highly specific, but is a good screening serologic test. A comparable qualitative serologic test, the rapid plasma reagin (RPR) test, is more widely used than VDRL in laboratories, because of increased specificity and ease of performing the assay.

CIE takes advantage of the net electric charge of the antigen and antibody being tested in a particular test buffer solution, when the two components migrate towards each other in a semisolid matrix under the influence of an electrical current. When the antigen and antibody meet in optimal proportions, a line of precipitation appears. The optimal performance of CIE tests depends on many variables, such as buffer pH, type of agarose gel, amounts of antigen and antibody placed, and amount of electrical current. These tests are difficult to develop and perform and are not commonly used.

COMPLEMENT FIXATION TEST

Complement fixation (CF) assays utilize two properties of complement: complement is inactivated in the presence of antigen–antibody complexes, and complement causes hemolysis of sheep red blood cells (RBC) coated with anti-sheep RBC antibodies (sensitized RBCs). In this assay system, laboratory-derived antigen and patient's serum containing the antibody of interest are allowed first to react in the presence of excess complement, followed by addition of sensitized RBCs to detect residual complement. Hemolysis indicates that complement was present and therefore antigen–antibody complexes were not formed in the reaction. Useful for detecting and quantitating antibody, CF is a test method used in reference laboratories for detecting infections due to *Mycoplasma pneumoniae*, *Chlamydia* and *Chlamydophila* spp., and *Coxiella burnetii*. The CF assay is a technically difficult serologic test and it has been replaced by the use of other simpler methods in most laboratories.

IMMUNOFLUORESCENCE ASSAYS

Due to increased specificity, indirect IF is the preferred technique of IF for detection of specific antibodies in patient serum. In these tests, specific microbial antigens are affixed to the surface of the microscope slide, on which serially dilutions of patient serum are added to form antigen–antibody complexes. After removal of unbound antibodies from the slide surface, fluorescein-conjugated antihuman globulin (directed against human IgG or IgM antibody) is added, and the slide is visualized under fluorescent microscopy. Commercially available indirect IF tests are widely used for detection of antibodies against *Legionella* spp., *B. burgdorferi*, *C. trachomatis*, *M. pneumoniae*, *Rickettsia* spp., and *Ehrlichia* spp.

ENZYME IMMUNOASSAYS

Using specific antigen immobilized on the surface of plastic wells, bead, or some other solid matrix, the antibody of interest in patient serum can be separated from other nonspecific antibodies, captured and quantified according to the intensity of the color produced from the enzymatic reaction. Various EIA are available commercially for detecting specific antibodies to *B. burgdorferi*, *H. pylori*, *M. pneumoniae*, chlamydiae, and other bacteria.

RADIOIMMUNOASSAY

Radioimmunoassay (RIA) is performed as a capture assay, such as that for ELISA, or as a competitive assay. Radioactively labeled antigen or antibody is used to quantitate the amount of antigen–antibody complexes formed. In the competitive assay, the antibody of interest in patient's serum is measured by its ability to compete with laboratory-prepared radiolabeled antibody for the antigen. The antigen–antibody complexes are

precipitated and separated from free antibody, and radioactivity is measured for both fractions. The amount of serum antibody is determined from standard calibration curves obtained from testing known quantities of competing antibody. RIA has been largely replaced by other equally sensitive methods, such as ELISA and indirect IF test, that are not associated with the disposal problems of radioactive reagents and the health hazards of radioactive exposure.

WESTERN BLOT IMMUNOASSAY

This assay involves separating microbial proteins (antigens) by electrophoresis according to molecular weight or electrical charge in a two-dimensional agarose gel matrix. These protein 'bands' are then transferred (blotted) from the gel on to a membrane (e.g. filter paper, nitrocellulose, nylon) to immobilize the proteins. When allowed to react with patient's serum, antibodies will bind to the immobilized proteins and are visualized as bands on the membrane with an enzyme-conjugated antihuman antibody. Western blot assays are mainly used for the confirmation of microbial antigen-specific antibodies in sera of patients who usually produce numerous cross-reacting antibodies in response to certain infections, such as Lyme disease.

BACKGROUND

For a variety of reasons, molecular diagnostic tests are being increasingly used for the diagnosis of infectious diseases. Advances in testing formats, including automated specimen preparation instrumentation and rapid amplification and detection technologies, have enabled the introduction of molecular microbiologic testing into even the most routine diagnostic laboratories. For some infections (e.g. herpes simplex viral encephalitis), molecular testing is *the* diagnostic approach of choice. For others, such as hepatitis C virus (HCV) infection, aside from serologic testing (which detects the host's immune response to the infectious agent), molecular diagnostics are routinely used. Even for infectious agents where conventional tests exist (e.g. culture for *Bordetella pertussis*), molecular diagnostic tests are increasingly favored because of improved sensitivity and speed as compared with conventional approaches (Sloan et al. 2002). Besides qualitative detection of microbes in clinical specimens, nucleic acid technologies are also used to quantify microorganisms (e.g. human immunodeficiency virus-1 (HIV-1)) in clinical specimens, to classify microorganisms isolated from clinical specimens, to detect and characterize antimicrobial resistance, and for epidemiology studies.

Nucleic acid amplification technologies have enabled substantial advances in the diagnosis of infectious disease agents because of their ability to detect small amounts of nucleic acid in a wide variety of clinical specimens. Molecular assays are independent of the presence of viable (e.g. able to be cultured) microorganisms. Quantification of microbial nucleic acid in patient specimens enables myriad potential innovations in clinical practice including assessment of disease severity, progression and response to therapy. Quantification of RNA levels is valuable both for measuring organisms with genomic RNA (e.g. HIV-1), and, potentially, for studies of microbial and host gene expression.

The polymerase chain reaction (PCR) was the first nucleic acid amplification technique to be broadly applied to the molecular detection of microorganisms and is a standard method used in clinical microbiology laboratories today. Since the original description of

PCR, numerous technological advances have facilitated its application to routine clinical molecular microbiology diagnostics. Additionally, a number of non-PCR amplification molecular methods are commonly used in clinical microbiology laboratories.

Although molecular tests substantially enhance diagnostic capabilities, as with any laboratory test, results should be interpreted within the clinical context and on the basis of individual assay performance characteristics. Clinical research and strict adherence to guidelines for method validation are needed to compare molecular diagnostic techniques with conventional methods, to validate molecular approaches where comparable conventional techniques are unavailable, and to determine the clinical usefulness of molecular diagnostic testing.

Although molecular diagnostic tests have classically been considered more expensive (i.e. 'boutique' tests) than conventional diagnostic techniques, the ease with which molecular tests can now be performed and the rapid results generated enable timely diagnosis, resulting in overall savings. Cost savings may be realized as rapid diagnoses prevent invasive diagnostic procedures, limit unnecessary or potentially toxic treatment, shorten hospital stays, replace labor-intensive conventional (e.g. cell culture) methods, and/or shorten hands-on laboratory technologist time. Early detection of contagious diseases, such as pulmonary tuberculosis, using molecular techniques would also limit the spread of infection.

ASSAY PERFORMANCE

Molecular techniques developed in research settings have been applied as 'in-house' developed assays in many clinical microbiology laboratories. The reason for this is that for many microorganisms, commercial assays are unavailable. Furthermore, it is relatively easy for laboratories with research and development expertise to develop and validate their own molecular assays based on nucleic acid amplification technology. The downside is that results derived from such assays may not be comparable from laboratory to laboratory, while no universal standards exist for these assays. The National Committee for Clinical Laboratory Standards (NCCLS) published guidelines for molecular diagnostic methods for infectious diseases in 1995 (Enns et al. 1995) and for quantitative molecular methods for infectious diseases in 2001 (Madej et al., 2001). Strategies to provide quality and to standardize molecular diagnostic tests include laboratory requirements for certification, proficiency surveys, and checklists, such as those published by the American College of Pathologists (www.cap.org/html/ftpdirectory/checklistftp.html) (College of American Pathologists 2003). The availability of state-of-the-art Food and Drug Administration (FDA)-approved commercial molecular diagnostic assays substantially contributes to interlaboratory standardization. A limited number of nucleic acid amplification assays for detection of microbes in human specimens are currently available (Table 1).

In order to understand and interpret molecular microbiology diagnostic tests, certain universal assay parameters must be defined (see also Wolk et al. 2001). Analytical sensitivity, also referred to as the lower limit of detection, refers to the lowest number of microorganisms that can be reproducibly detected by the assay. Clinical sensitivity is the proportion of specimens that yield positive test results from patients who have a specified clinical entity. High analytical sensitivity may exist with inadequate clinical sensitivity if false-negative results occur because the target nucleic acid copy number in the clinical specimen is low. Analytical specificity refers to the ability of the test to detect only the microorganism it purports to measure. Clinical specificity is the proportion of specimens that yield negative results from patients who do not have a specified clinical entity.

For quantitative molecular microbiologic diagnostic testing, additional parameters bear consideration. The linear range refers to the quantitative spectrum over which the test provides results detecting a direct relationship between input target concentration and output signal. The upper and lower limits of quantification reflect the upper and lower ends of this linear range. The lower limit of quantification of a quantitative assay may be higher than the analytical sensitivity of a qualitative assay, confusing the interpretation of results. This is exemplified by molecular testing for HCV. The lower limit of quantification of the VERSANT^{TM} HCV RNA 3.0 assay (bDNA) (Bayer Healthcare LLC, Tarrytown, NY, USA), a quantitative HCV RNA assay, is higher than the lower limit of detection of the COBAS AMPLICOR^{TM} HCV Test, version 2.0 (Roche Diagnostic Corporation, Indianapolis, IN, USA), a qualitative HCV RNA assay (Germer et al. 2002).

Precision refers to the agreement between replicate measurements of the same material. Accuracy refers to the ability of a method to reliably determine the true value of the particular target. The tolerance limit is the difference between two results that can be considered to be significantly different and is the sum of the biological variation in quantification and intra-assay variability. For quantitative assays of HIV-1 RNA, for example, increases or decreases in the RNA titer of at least threefold typically reflect biologically relevant changes in the level of viral replication (Wolk et al. 2001).

In an effort to standardize quantitative testing, interlaboratory collaborations with the World Health Organization have established the World Health Organization International Standards, which are standard reference materials with concentrations expressed as international units (IU) per milliliter, which can be used to calibrate,

validate, and compare different quantitative molecular assays measuring very similar targets in the same pathogen. Currently, standards exist for HIV-1, hepatitis A virus, hepatitis B virus (HBV), HCV, and parvovirus B19. Further information is available from the National Institute for Biological Standards and Controls (www.nibsc.ac.uk).

SPECIMEN SUITABILITY

For each molecular diagnostic assay, criteria for the appropriate specimen, including the optimal specimen source, specimen volume, collection method, transport and storage conditions, specimen stability, and nucleic acid preparation method must be considered. The sensitivity and specificity of an assay may vary considerably if any of these conditions are altered. The choice of specimen plays a key role in the performance and interpretation of test results. Typically, molecular microbiologic assays are clinically validated using one or more specimen sources (e.g. spinal fluid, blood) that may contain a target organism. For blood specimens, sensitivity and specificity may vary depending on the specific fraction (i.e. plasma, serum, whole blood, various leukocyte fractions) analyzed. The viral load, for example, will vary depending on the specific specimen tested; plasma or serum is typically used for detection of HBV DNA, HCV RNA, or HIV-1 RNA. The volume of specimen from which nucleic acid is extracted can also affect the sensitivity and specificity of the assay. Traditional molecular diagnostic tests typically analyze relatively small specimen volumes (e.g. 200 µl or less). For low-copy-number targets, increasing the amount of specimen analyzed may increase sensitivity (Germer et al. 2003).

Inhibitory substances may interfere with various steps in molecular diagnostic assays yielding false-negative results (Wolk et al. 2001). Inhibitors present in the patient specimen (e.g. hemoglobin, lactoferrin, immunoglobulin G, bile salts, polysaccharides, proteinases, urea, leukocyte DNA) or introduced during specimen collection or processing (e.g. ethylene diamine tetraacetic acid (EDTA), heparin, guanidinium HCl, sodium dodecylsulfate) may interact with nucleic acid or critical enzymes (e.g. DNA polymerase) to prevent target amplification or remove reaction components (e.g. metals) affecting enzymatic substrates (Al-Soud et al. 2000, 2001). The presence of inhibitors, and therefore the negative predictive value of the assay, can be assessed in several ways. The patient's specimen can be spiked with known target nucleic acid and the spiked specimen tested along with the native patient specimen. Alternatively, internal amplification controls can be added to the patient specimen and amplified concurrently with the target nucleic acid. Detection of housekeeping genes (e.g. human β-globin, interleukin-2) has been incorporated into some assays to confirm the presence of human cellular DNA in the patient specimen. Although this approach can be used to assess the presence of inhibitors, since the amount of human DNA generally exceeds the amount of microbial DNA, this approach to inhibitor detection may be less sensitive than the use of spiked specimens or internal amplification controls.

SPECIMEN PREPARATION

Specimen preparation techniques are a critical component of clinical molecular microbiologic diagnostics (Wolk et al. 2001). Optimal specimen preparation efficiently releases microbial nucleic acid while preserving its integrity, removes inhibitors, sterilizes the specimen of viable organisms, concentrates the target nucleic acid into a small volume (if appropriate), and places the target into an environment suitable for amplification. For many assays, specimen preparation may be more labor-intensive and time-consuming than actual amplification and detection. Many specimen-preparation

methods exist; some require considerable technical skill, as they are labor-intensive, nonstandardized, and prone to manipulation steps where template cross-contamination may occur. A detailed discussion of available nucleic acid preparation methods for molecular microbiology diagnostic purposes is beyond the scope of this chapter. In general, specimens are treated with alkaline pH, chaotropic agents, sonication, heat, detergents, freeze–thaw cycles, and/or proteolytic enzymes to disrupt the cell membranes and cell walls and to release nucleic acid. Thereafter, nucleic acid may or may not be extracted with organic solvents, adsorbed to silica in the presence of chaotropic agents such as guanidinium salts, and/or precipitated in the presence of salts and alcohol. Nucleic acid capture technologies such as automated silica-based membrane capture technologies or magnetic bead nucleic acid capture can also be used. For specimens that represent a potential biohazard for laboratory personnel (e.g. specimens submitted for testing for agents of bioterrorism), autoclaving the specimen prior to molecular testing (121°C, 15 min, 20 psi) enables inactivation of potentially viable hazardous infectious agents without destruction of nucleic acids (Espy et al. 2002).

Automation of specimen preparation provides rapid, cost-effective, and consistent results. Several automated extraction instruments are available. The ability to interface with high-throughput amplification systems is an important advance of these new automated extraction systems. For example, the MagNA Pure LC (Roche Diagnostic Corporation) integrates with the LightCycler® PCR instrument (Roche Diagnostic Corporation) and can be used to automate or partially automate both extraction and PCR setup processes (Espy et al. 2001).

PROBE HYBRIDIZATION

Nucleic acid probes are short segments of single-stranded DNA or RNA that can be 'labeled' (i.e. with antigen, chemiluminescent substrate, radioisotope, enzyme) and can bind with high specificity to complementary (target) nucleic acid sequences. In situ hybridization uses intact cells (e.g. in formalin-fixed, paraffin-embedded tissue) containing specific DNA or RNA as a target for probe hybridization. The technique allows visualization of infected cells within tissue and thereby association of hybridization results with other morphologic changes. Because in situ hybridization is not an amplification-based technique, sensitivity may be limited. Probe-based commercial kits, such as the PACE® System from Gen-Probe, Inc. (San Diego, CA, USA), which directly detects *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in clinical samples, produce results that are generally equivalent to culture techniques but in much less time. Nucleic acid probes are also an integral component of the amplification techniques described below.

POLYMERASE CHAIN REACTION

PCR is the original and most widely used nucleic acid target amplification technology. A buffered reaction mixture containing the target DNA sequence (template), oligonucleotide primers, thermostable DNA polymerase, deoxynucleotide triphosphates (dNTPs), and magnesium or manganese ions with or without other additives, is placed into a thermal cycler, which heats and cools the components, exposing them to consecutive cycles of alternating temperatures (Wolk et al. 2001). In each cycle, three processes occur:

1. Denaturation: heating to high temperatures to separate double-stranded DNA into single strands.
2. Primer annealing: lowering the temperature to allow for synthetic oligonucleotide primers to anneal to the single-stranded DNA and create a partial double strand.
3. Primer extension: addition of dNTPs to the 3′ ends of the bound primers by DNA polymerase, thereby creating a new synthetic piece of double-stranded DNA, which is complementary to the original template strand.

With the exception of the first cycle, the amount of target DNA theoretically doubles with each cycle, resulting in an exponential increase in the quantity of amplified DNA until the reaction reaches a plateau phase due to depletion of reaction components. The amount of product that accumulates is $N_{\text{total}} = N_{\text{initial}}(1 + Y)^X$, where Y is the efficiency per cycle. Examples of some specific types of PCR are shown in Table 2.

Following amplification, amplified DNA is detected. Many of the classic methods for detection of amplified DNA are manual, requiring manipulation of amplified DNA and adding substantial risk of contamination to subsequent PCR reactions, rendering them suboptimal for use in clinical laboratories. Agarose or polyacrylamide gel electrophoresis use electric current to separate DNA fragments according to molecular size; DNA fragments are visualized by staining with a DNA binding dye (e.g. ethidium bromide). Generally, agarose or polyacrylamide gel electrophoresis (alone) does not provide ideal sensitivity or specificity for clinical microbiology diagnostic testing. To increase specificity, the amplified DNA can be digested with a restriction enzyme prior to electrophoresis; the resultant restriction digest yields a unique pattern of DNA fragments by gel electrophoresis. To increase sensitivity as well as specificity, PCR products may be subjected to Southern blotting followed by probe hybridization. Briefly, DNA from a gel is transferred to a synthetic membrane, on which labeled oligonucleotide probes

Table 2 *Modifications of the polymerase chain reaction (PCR)*

Modification	Principle
Broad-range bacterial PCR	Use of PCR primers targeted to highly conserved regions of bacterial DNA such that, depending on the primer sets used, the target can be amplified from most bacteria
In situ PCR	Amplification of DNA (or complementary DNA) inside an intact cell (e.g. in a paraffin-embedded tissue section) to determine the disposition of a microbe within tissue
Multiplex PCR	Use of two or more primer sets in the same reaction mix to identify multiple microorganisms or multiple nucleic acid targets within one microorganism in a single assay
Nested PCR	Use of one set of primers followed by reamplification with a second set of primers, internal to the first
Quantitative PCR	A technique used to assess the amount of a microbe present in a patient specimen
Semiquantitative or limiting dilution PCR	Titer determination of target template by endpoint specimen dilution prior to PCR
Quantitative competitive PCR	Use of an internal quantitative standard (or calibrator) in the amplification reaction along with the target sequences. The standard competes with target sequences in the PCR reaction. The quantity of internal quantitative standard amplified correlates inversely with the quantity of target
Real-time quantitative PCR	Quantitation of amplified target determined by cycle number at which the amplification product is first detected (using fluorescence detection) in comparison with a quantitative standard
Randomly amplified polymorphic DNA (RAPD) analysis (arbitrarily primed PCR)	Random amplification of segments of target DNA using arbitrary primers that do not have any known homology to the target sequence. Amplified DNA is visualized on a gel following electrophoresis and patterns are compared to one another
Real-time PCR	Simultaneous amplification and amplification product detection using fluorescence detection (Figure 1)
Repetitive element sequence-based PCR	Uses consensus sequence-based PCR primers to amplify DNA sequences located between successive repetitive elements
Reverse transcriptase-PCR (RT-PCR)	Uses reverse transcriptase to create complementary DNA from an RNA target. The complementary DNA is then amplified by PCR Used to detect RNA (either because an infectious agent's nucleic acid is naturally present as RNA, or to detect transcribed microbial DNA as a marker of active infection)

complementary to an internal region of the amplified sequence are subsequently hybridized to the DNA. Hybridized probes are then detected by one of a variety of methods (e.g. autoradiography, chemiluminescence). Another option for detection is incorporation of various chemicals (e.g. digoxigenen-11-dUTP) into the DNA during amplification. Amplified DNA can then be detected on the membrane by a second chemical reaction (e.g. anti-digoxigenin antibody:alkaline phosphatase conjugate and a chemiluminescent substrate).

Besides membrane-based amplified DNA detection methods, a number of other approaches can be used (Wolk et al. 2001). Probes can be bound to microtiter plate wells or beads to capture amplified DNA. A specific 'signal' probe can then be added to react with the captured target nucleic acid. In the PCR-enzyme-linked immunosorbent assay, amplified DNA containing digoxigenen-11-dUTP is hybridized to oligonucleotide capture probes labeled with biotin. Biotinylated DNA hybrids are then bound to a streptavidin-coated microtiter plate so those specific DNA complexes can be detected in a microtiter plate format.

Solution- (liquid-) phase hybridization is another option. An example is the hybridization protection assay wherein chemiluminescent probes hybridize to original target nucleic acid or to amplified DNA, which have been produced by a previous amplification method. Following chemical destruction of the nonhybridized probes, the chemiluminescent label, protected within the hybrid, reacts under specific conditions to produce light, which can be measured by a luminometer.

Other methods that can be used to separate, quantify, or identify amplified DNA include high-performance liquid chromatography, mass spectrometry, and DNA sequencing methods.

Homogeneous or real-time PCR assays incorporate amplification and detection within one closed system. Such assays are being used increasingly in clinical microbiology laboratories because of their rapid turnaround time and the lack of postamplification manipulation and

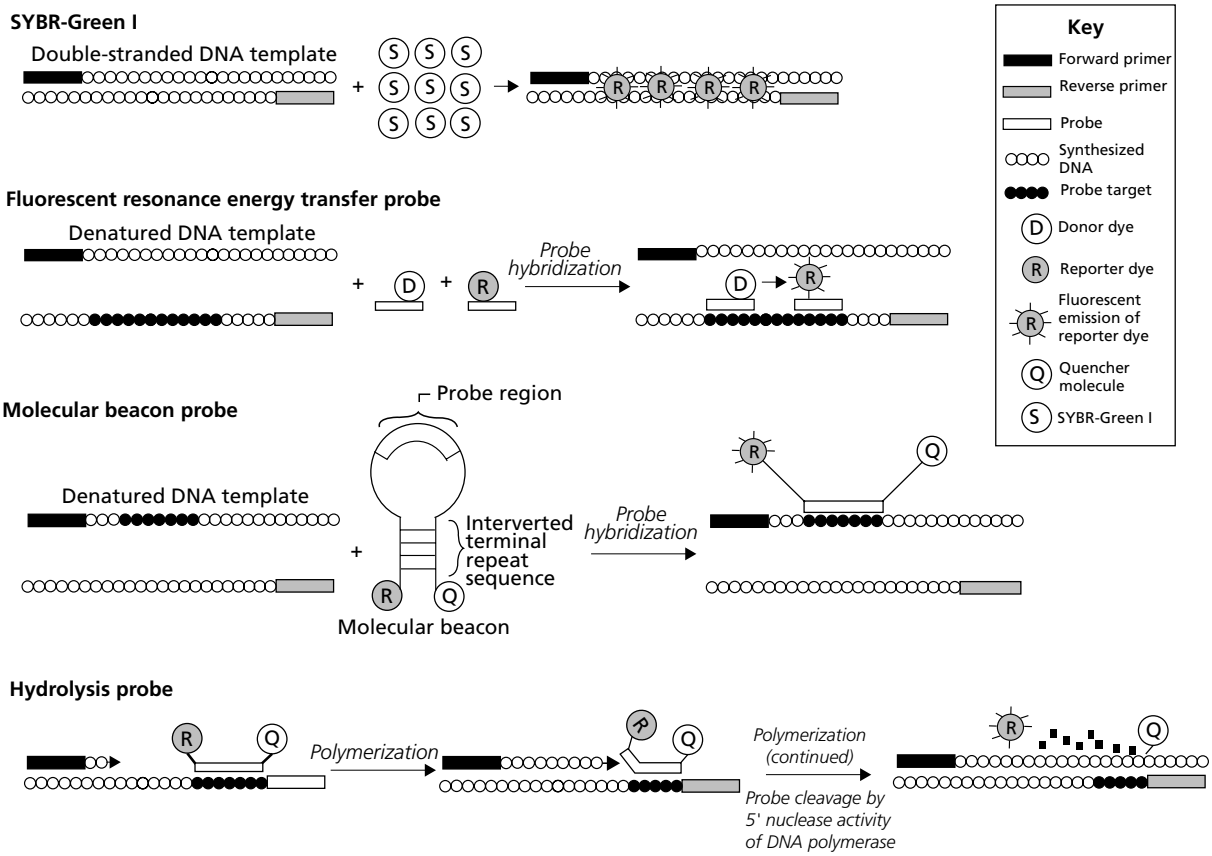

Figure 1 *Real-time polymerase chain reaction detection (see text for details).*

contamination risk inherent to traditional methods. These methods are reviewed in detail below.

CONTAMINATION AND CONTAMINATION CONTROL

The strength of nucleic acid amplification is high sensitivity (Wolk et al. 2001). Because of this sensitivity and the large amount of amplified DNA generated, prevention of nucleic acid contamination of other molecular assays performed in the same laboratory is essential. Sources of contamination include crossover contamination from specimens containing large numbers of target molecules or, most importantly, from manipulation of amplified nucleic acid. Amplified nucleic acid may contaminate reagents, laboratory surfaces, as well as the laboratory personnel themselves. The setup of the laboratory should be such that the movement of patient specimens and personnel proceeds from pre-amplification to postamplification areas. Separate areas (preferably rooms) for reagent preparation, sample processing, and amplification and detection are ideal. Besides these physical approaches to contamination control, enzymatic (e.g. uracil-*N*-glycosylase (UNG)) or photochemical (e.g. isopsoralen) methods of inactivating amplified DNA may be applied (Wolk et al. 2001). For enzymatic inactivation utilizing UNG, dUTP in lieu of dTTP is incorporated into the amplified DNA such that amplified target will contain dUTP (whereas native target contains dTTP). Any dUTP-containing amplification products (i.e. contaminants from prior PCR reactions) are cleaved by UNG prior to amplification in subsequent reactions. For photochemical inactivation, amplified DNA is generated in the presence of isopsoralen. Inactivation occurs by postamplification irradiation of the reaction vessel with ultraviolet light prior to opening the reaction vessel; irradiation causes the isopsoralen to modify the amplified DNA such that the DNA is unable to serve as a template for further amplification but is still capable of hybridization in various detection formats. As discussed above, closed-system PCR reactions can also be used to prevent contamination.

All PCR testing should include a sufficient number of negative controls processed along with patient specimens to provide a measure of assurance that assay contamination is not occurring. For each assay, a positive control in low copy number should also be included.

RAPID REAL-TIME PCR

A significant advance in PCR technology is the development of rapid PCR with simultaneous probe detection,

so-called 'real-time PCR' (Wolk et al. 2001). In real-time PCR assays, amplification and product detection occur simultaneously in the same sealed reaction vessel, tube, or well. A fluorescent signal generated by specific binding of chemicals or probes to amplified DNA is used for real-time monitoring of production of amplified DNA.

Because amplification and product detection are performed in the same vessel, these systems can be closed. Closed PCR systems lessen the risk of contamination by avoiding postamplification manipulation and lessen the needs for extensively engineered molecular laboratory space. Nevertheless, careful attention to unidirectional workflow, amplification product control, and amplification product-inactivation protocols remain important. Template carryover contamination can still occur, and liberation of amplified DNA through broken reaction vessels can lead to contamination events unless DNA-inactivating methods are included in the assay.

Many real-time PCR systems have incorporated technology that enables a dramatic reduction in the time required for assay performance. For example, realtime PCR performed using the LightCycler® instrument (Roche Diagnostic Corporation) can be completed in 30 to 40 min (versus several hours to days for conventional PCR and amplification product detection).

Several fluorescent chemistry approaches can be utilized to detect amplified DNA in real time (Figure 1) (Wolk et al. 2001). Real-time monitoring of nonspecific fluorescent dye (e.g. SYBR-Green I) incorporation can be used (Figure 1). Nonspecific dyes bind to double-stranded DNA generated during PCR and emit fluorescence, which can be monitored by various detection systems. Since the dyes bind to all nonspecific amplification products produced in the reaction, as well as to primer-dimers, dye incorporation alone does not ensure detection of a specific PCR product. To improve specificity, melting-curve analysis can be performed. The amplified product will have a characteristic melting temperature (Tm), the sequence-dependent temperature at which half of the nucleic acid strands become separated in solution, differentiating it from nonspecific amplification products. To further ensure more specific hybridization and product identification, protocols that incorporate specific internal probes are used. Several internal probe formats exist. They include dual hybridization (fluorescence resonance energy transfer (FRET)) probes, molecular beacon probes, and hydrolysis (e.g. TaqMan™) probes (Figure 1).

Dual hybridization uses two probes (one coupled to a fluorescent donor dye and the other to a fluorescent reporter dye) designed to recognize single strands of amplified DNA internal to the primer binding sites (Figure 1). As DNA is amplified, probes hybridize to amplified DNA in close proximity to one another (usually one to five nucleotides apart) during the annealing step. An external light source then stimulates the fluorescent donor dye, and energy emitted from the donor dye excites the fluorescent reporter dye to emit a specific wavelength of light.

Molecular beacons are single-stranded oligonucleotide probes that are created using a specific hybridization probe sequence, which is flanked by two inverted terminal repeat sequences such that a stem-loop (or hairpin) structure is formed (Figure 1). As the molecular beacon probe opens and binds to a denatured DNA template, a quencher molecule (located on one arm) is removed from proximity of a fluorescent reporter dye (located on the other arm), allowing the reporter dye to fluoresce upon stimulation from an external light source. In contrast, while the probes are in a hairpin formation, the reporter dye and quencher molecules are proximal and fluorescence is quenched.

Using FRET-based probe pairs or molecular beacons, melting-curve analyses can be performed by monitoring the Tm at which the probe separates from the amplified DNA. This analysis permits specific identification of the amplified DNA. After PCR is performed, the amplified DNA is heated to its denaturation temperature and diminished fluorescent reporter signal is observed. Because mismatches, such as point mutations or polymorphisms, combined with other amplified DNA characteristics, such as fragment size and percentage GC content, can affect the Tm of the probe:DNA hybrid, Tm curves can be used to distinguish different PCR products including those with as few as 1 bp difference.

TaqMan™ chemistry combines DNA polymerase with 5′-exonuclease activity and a linear oligonucleotide hybridization probe carrying both a fluorescent reporter dye and a quencher molecule (Figure 1). The hybridization probe binds to the denatured amplified target DNA strands. Fluorescence of the reporter dye is prevented (quenched) by its proximity to the quencher molecule. After each annealing cycle, DNA polymerase, with 5′-exonuclease activity, extends the specific target strand and cleaves the hybridization probe, which is specifically bound to the strand. The exonuclease activity fragments the probe, separating the quencher molecule from the reporter dye. The cleaved reporter dye fluoresces when stimulated from an external light source. If specific amplification of target DNA has occurred along with cleavage of the hybridization probe, reporter dye fluorescence increases and accumulates with each PCR cycle. Melting-curve analysis cannot be performed with TaqMan™ probes.

While SYBR-Green I, TaqMan™, FRET, and molecular beacon technology can be used to monitor real-time endpoint (qualitative) PCR, these techniques can also be used to quantify target nucleic acid. The amount of microbe-specific nucleic acid in a given patient specimen is determined by comparing target amplification signal to internal or external quantitative standards and, through mathematical algorithms, determining the exact number of amplification cycles at which amplified DNA is detected above a baseline or threshold value. Real-time

quantitative PCR assays offer advantages over nonreal-time semiquantitative PCR approaches (Table 2), which analyze endpoint amplification products at a point when net synthesis is significantly reduced, inhibitory effects accumulate, and differences in the initial starting template concentrations are masked.

Several automated real-time PCR instruments that use the aforementioned technologies are currently available: LightCycler® (Roche Diagnostic Corporation), SmartCycler® (Cepheid, Sunnyvale, CA, USA), ABI PRISM® Sequence Detection Systems (SDS) (Applied Biosystems, Foster City, CA, USA), iCycler (Bio-Rad Laboratories, Hercules, CA, USA), Mx4000™ Multiplex Quantitative PCR System (Stratagene, La Jolla, CA, USA), and Rotor-Gene™ (Corbett Research, Sydney, Australia). Real-time PCR assays are run on highly specialized automated instruments that include optical systems to excite fluorescent dyes and detect fluorescent emissions at a variety of wavelengths specific to the dyes used. These systems have the potential to provide rapid results and to facilitate multiplex PCR through the use of different fluorophores.

NUCLEIC ACID SEQUENCE-BASED AMPLIFICATION AND TRANSCRIPTION-MEDIATED AMPLIFICATION

Nucleic acid sequence-based amplification (NASBA) and transcription-mediated amplification (TMA) are similar isothermal reactions that use a RNA target as the substrate for reverse transcriptase, creating a complementary DNA (cDNA) strand from the RNA template (Figure 2) (Wolk et al. 2001). RNA from the resulting RNA:DNA hybrid is then degraded by RNAse H, and cDNA is used as a template for RNA polymerase, producing multiple RNA copies from the cDNA. Results can be qualitative or quantitative. Modifications of TMA also exist for use with DNA targets.

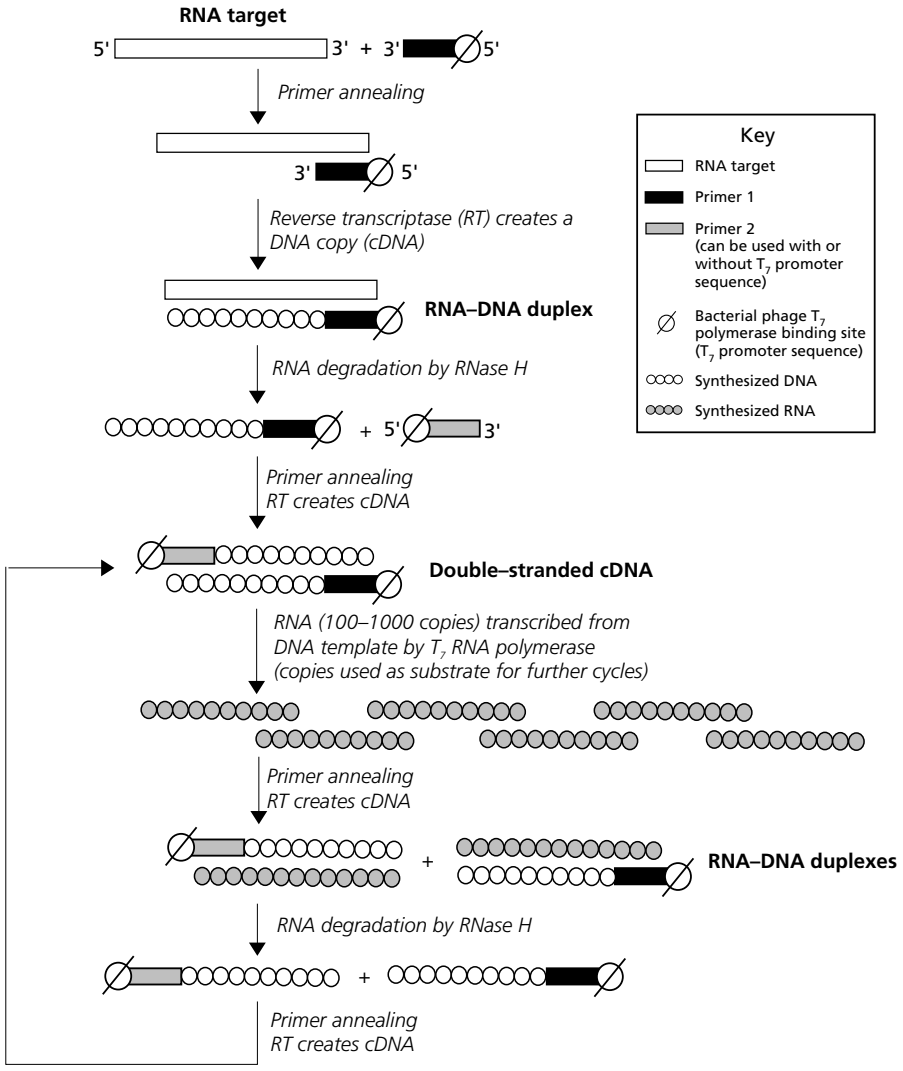

Figure 2 *Transcription-based amplification systems: nucleic acid sequence-based amplification (NASBA) and transcription-mediated amplification (TMA) (see text for details). Reprinted with permission from Wolk et al. 2001.*

NASBA uses separate reverse transcriptase and RNase H enzymes, whereas TMA uses a reverse transcriptase enzyme with endogenous RNase H activity. Gen-Probe, Inc. currently offers commercial TMA assays for detection of *Mycobacterium tuberculosis* and *Chlamydia trachomatis*. A TMA assay for qualitative detection of HCV RNA is available from Bayer Healthcare LLC. BioMérieux (Boxtel, The Netherlands and Durham, NC, USA) offers NASBA testing for quantitative detection of HIV-1 RNA and qualitative detection of CMV pp67 mRNA.

STRAND-DISPLACEMENT AMPLIFICATION

Strand-displacement amplification (SDA) is an isothermal amplification technique in which primers, containing both a target-specific region and a hemimodified restriction enzyme site, combine with a DNA polymerase to create a synthetic double-stranded DNA that contains the restriction enzyme site (Figure 3) (Wolk et al. 2001). A restriction enzyme generates a site-specific 'nick' in one of the two strands of double-stranded DNA. Once the strand is nicked, DNA polymerase initiates synthesis at the 3′ end of the nick site to create a new DNA strand. Because the DNA polymerase used is deficient in 5′ to 3′ exonuclease activity, it does not destroy the existing strand as it polymerizes the new strand; it simply displaces the downstream nontemplate strand. Each displaced strand is then available to anneal with more primers and the process continues with repeated nicking, extension, and displacement of newly formed DNA strands. The entire process results in exponential amplification of the original DNA target.

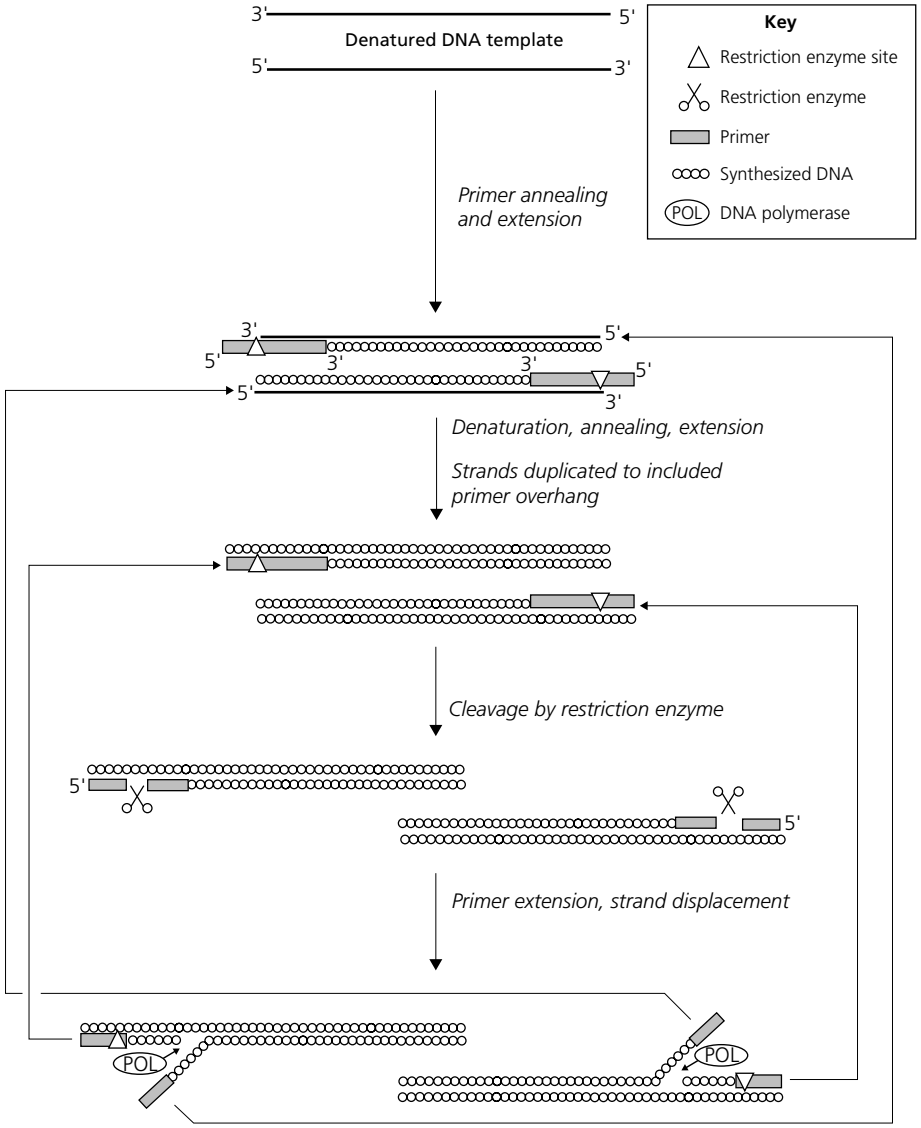

Figure 3 *Strand-displacement amplification (SDA) (see text for details). Redrawn with permission from Wolk et al. 2001.*

HYBRID CAPTURE ASSAY

In the hybrid capture assay, an RNA or DNA probe hybridizes to a DNA or RNA target, respectively (Wolk et al. 2001) (Figure 4) . Hybrids are captured on a solid phase coated with capture antibodies specific for the RNA:DNA hybrids (duplexes). Captured hybrids are detected using chemiluminescence. Digene Corporation (Silver Spring, MD, USA) is a manufacturer for hybrid capture assays for human papilloma virus (HPV), CMV, HBV, *C. trachomatis*, and *N. gonorrhoeae*.

LIGASE CHAIN REACTION

In the ligase chain reaction (LCR), DNA template is denatured and subsequently hybridized to probes that are located next to each other on the target strand (Figure 5) (Wolk et al . 2001). The hybridized probes are ligated (joined) by DNA ligase to form a ligation product that mimics one strand of original target sequence and can serve as a template for ligation of more probes. Successful ligation of the probes depends on the proximal positioning and perfect base pairing of the 3′ end of one probe with the 5′ end of the other to complete a complementary DNA strand. DNA polymerase and dNTPs are used to extend the probe and fill the gap region prior to ligation with DNA ligase. Accumulated ligation products are detected by incorporation of labeled probes.

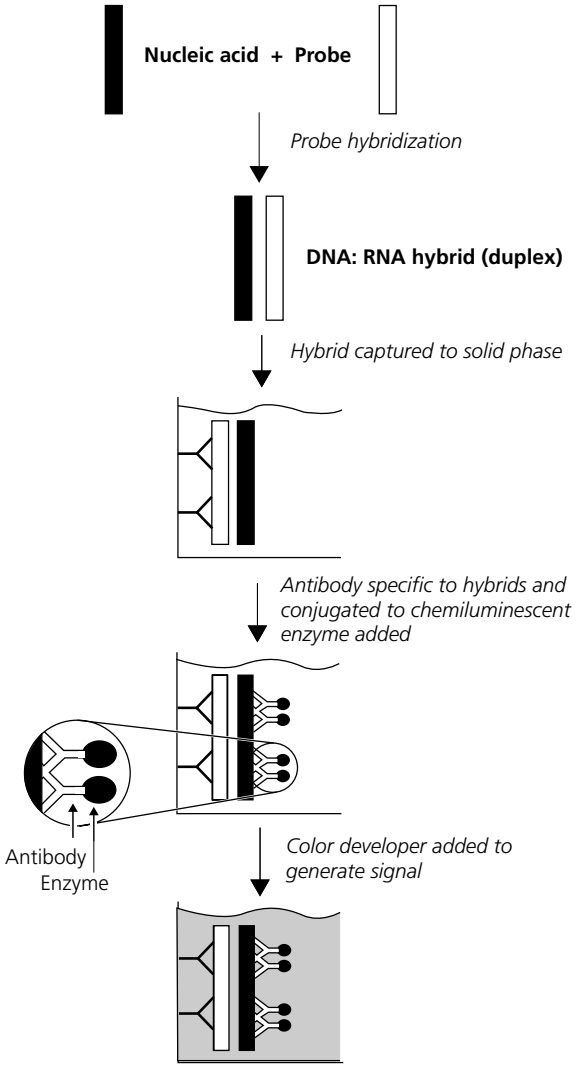

Figure 4 *Hybrid capture assay (see text for details). Reprinted with permission from Wolk et al. 2001.*

BRANCHED DNA ASSAY

Quantitative branched DNA (bDNA) assays are commercially available from Bayer for HBV, HCV, and HIV-1 (Table 1). With bDNA technology, organisms are disrupted, releasing nucleic acid to be captured by multiple capture probes that are bound to a solid surface (Figure 6) (Wolk et al. 2001). Target probes hybridize to both microbial nucleic acid and signal amplification multimer (branched DNA or bDNA). Finally, enzyme-labeled probes hybridize with bDNA structures. Detection occurs via a chemiluminescent process. The amount of signal generated is directly related to the amount of target nucleic acid present in the specimen.

CYCLING PROBE TECHNOLOGY

Cycling Probe Technology (CPT) (Velogene™; ID Biochemical, Vancouver, British Columbia, Canada) is an isothermal process that can be used to detect target DNA (Wolk et al. 2001). Commercial applications of CPT are available as Velogene test kits for methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE). Briefly, the technology utilizes a synthetic probe, a chimera of DNA-RNA-DNA, which is labeled at the 5′ end with fluorescein dye and at the 3′ end with a biotin molecule (Figure 7). The fluorescein/biotin-labeled probes are designed to anneal with a specific DNA template. Once the probes anneal, RNase H is added to cleave the RNA portion of the bound probe. The shorter, cleaved probe fragments will then dissociate from the target, releasing the target for use in subsequent cycles. In the presence of a specific target molecule, cleaved probes accumulate with each cycle. The test is designed so that a colorimetric reaction will occur in the presence of uncleaved probe; no color will occur in the presence of cleaved probes (specific target). To detect the presence or absence of cleaved probes, an antifluorescein antibody coupled to horseradish peroxidase (Ab/HRP) is added and the reaction is transferred to microtiter wells coated with streptavidin molecules. An alternative test using a nitrocellulose strip has been manufactured for detection of uncleaved probes. All probes will bind to streptavidin, but only the uncleaved probes will bind to the Ab/HRP. A substrate for horseradish peroxidase is added, and

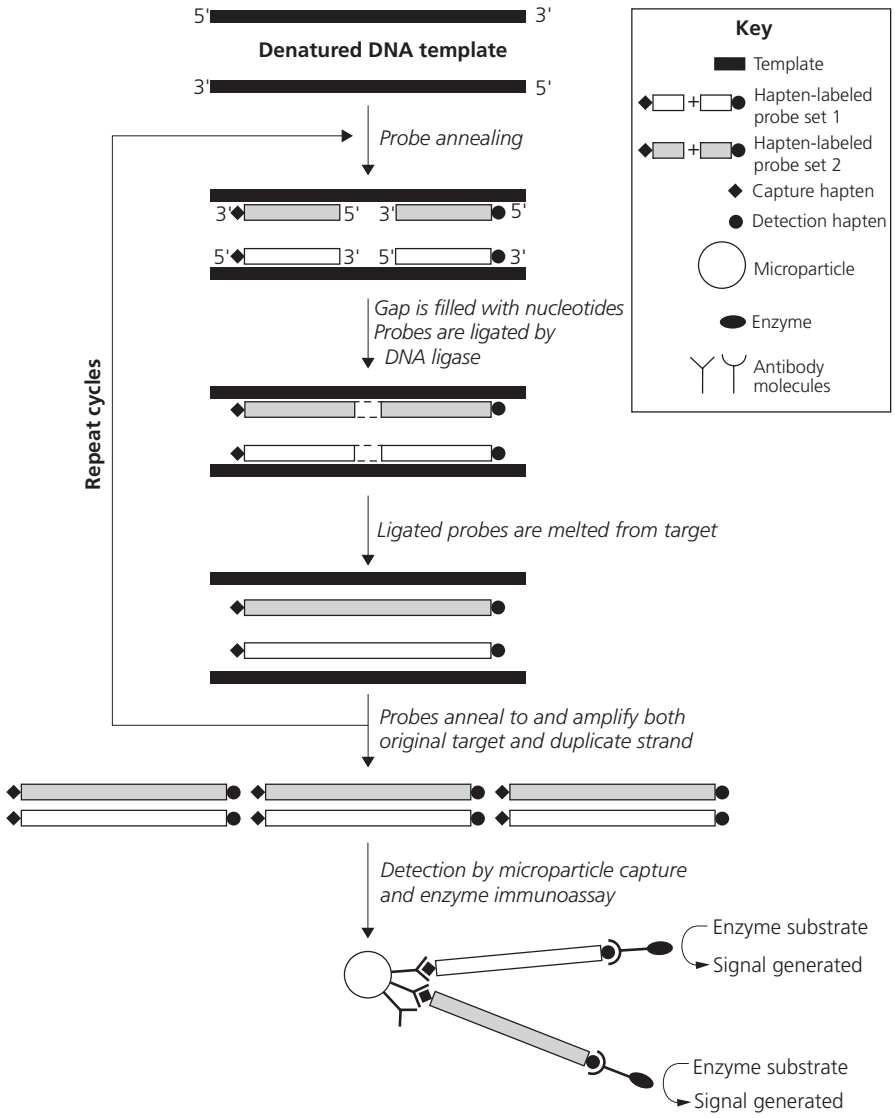

Figure 5 *Ligase chain reaction (LCR) (see text for details). Reprinted with permission from Wolk et al. 2001.*

color development is measured to determine the amount of uncleaved probe present in the well (or in the region of the strip). The color development is inversely proportional to the original amount of target DNA present.

NUCLEIC ACID SEQUENCING

Nucleic acid sequencing has several applications in the clinical microbiology laboratory (Wolk et al. 2001). For example, the technology can be used to determine HBV, HCV, HIV-1, and HPV genotypes, to determine the DNA sequences of bacteria and fungi for microbial classification postculture, and to identify mutations associated with resistance to antimicrobics.

Most DNA sequencing methods are based on a modification of Sanger dideoxynucleotide triphosphate (ddNTP) chain termination chemistry in which synthetic ddNTP molecules that lack 3′ hydroxyl groups normally present in the natural molecules are added to a DNA synthesis reaction (Figure 8) (Wolk et al. 2001). Whenever a ddNTP molecule is incorporated into the growing DNA strand (in lieu of the usual dNTPs), the synthesis reaction is terminated. For dye-terminator cycle sequencing, four different fluorescent dyes are incorporated into each of the four ddNTPs (ddATP, ddCTP, ddGTP, and ddTTP), and the end result is a collection of DNA fragments of different lengths labeled with different dyes depending on the terminal nucleotide. Reaction end products are separated by electrophoresis, excited and detected by a laser. The resulting digital data are processed into electronic DNA sequence data. Sequence data are analyzed by special computer software and are displayed either as linear strings of one-letter nucleotide codes or as a graphic electropherogram.

The generation of large numbers of DNA sequences has created new needs for archiving and updating

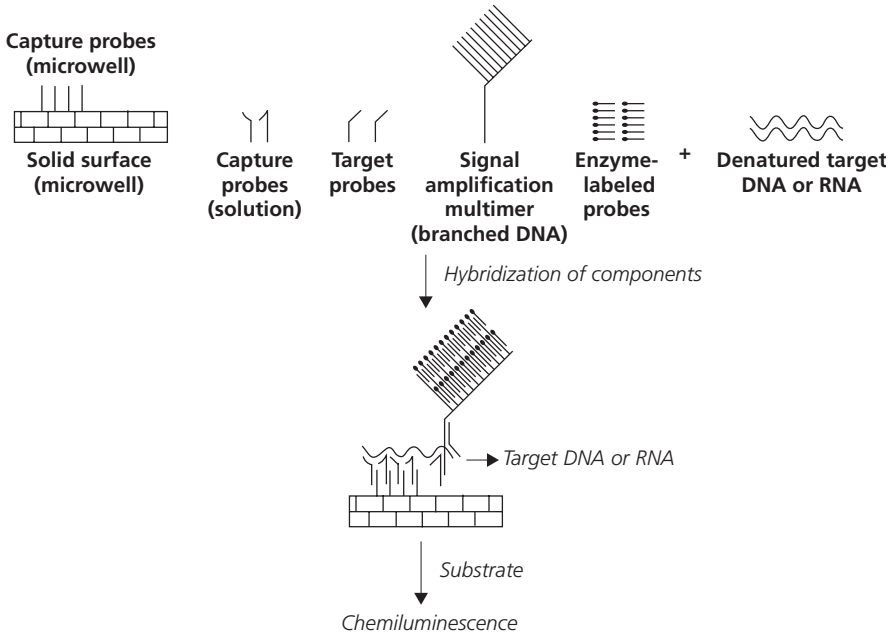

Figure 6 *Branched DNA (bDNA) signal amplification (see text for details). Redrawn with permission from Wolk et al. 2001.*

bioinformatics data and validated sequence information. Although several microbes have been sequenced, the vast majority of microbes, even clinically important microbes, have not yet been sequenced. Furthermore, although microbial genomic databases exist, there are limitations to these databases. The web-based genomic database, GenBank, established in 1988, is available as a national resource of molecular biology information from the National Center for Biotechnology Information (www.ncbi.nlm.nih.gov). Related databases such as the rRNA WWW server (www.oberon.rug.ac.be:8080/rRNA), the Ribosomal Database Project II (www.rdp.cme.msu.edu/html), the Institute for Genomic Research (www.rdp.cme.msu.edu/html), and the Ribosomal Differentiation of Medical Microorganisms (www.ridom.de) provide nonproprietary sources of genomic information (Wolk et al. 2001).

While public databases contain a wealth of information, certain caveats must be noted if the data are to be used by clinical microbiology laboratories (Wolk et al. 2001). The sequence data and the descriptive data included with each entry may not be peer-reviewed, so any use of the information contained in these databases must be made with caution. The quality of the sequence data can vary and some sequences may contain errors. Furthermore, although these are large databases, one cannot be assured that they contain information for every gene for every organism. For this reason, well-validated and comprehensive databases are needed for use in clinical microbiology laboratories. The commercially available MicroSeq® 16S rDNA Bacterial Sequencing kit (Applied Biosystems) combines a PCR and cycle sequencing kit that can be used with the commercially available MicroSeq® software and the commercially available MicroSeq® 16S rDNA database for organism identification. Although this approach is useful to aid in characterization of many organisms, its use is limited by the relatively small size of the MicroSeq® database.

Several commercial systems have been designed for nucleic acid sequencing and sequence analysis. The TRUGENE™ assays (Bayer Healthcare LLC) use dye primer chemistry (as compared with dye terminator chemistry) and a two-dye system in a proprietary (CLIP™) sequencing system. These assays identify mutations in the HIV-1 protease and reverse transcriptase genes, mutations in the HBV surface antigen and polymerase genes, and genotypes of HCV (based on the 5′ NC region) and HBV. Sequence data are obtained and compared with a proprietary sequence. Sequence data are regularly updated and interpreted using proprietary interpretation codes and software.

The line probe assay (VERSANT™ genotype LiPA assay, Bayer Healthcare LLC) is a modification of Southern blot technology in which reverse hybridization occurs with multiple specific nucleic acid probes arranged in a multiline format on a nitrocellulose strip (Mitchell et al. 2002). After PCR is performed using a biotinylated primer, the amplified DNA is hybridized to a strip containing immobilized oligonucleotide probes. Subsequently, streptavidin-alkaline phosphatase is used to detect the hybridized biotinylated amplified DNA. Alkaline phosphatase acts on a chromogenic substrate added to the system to enable color development at locations on the strip where specific DNA is bound. The result is a fingerprint of the hybridization

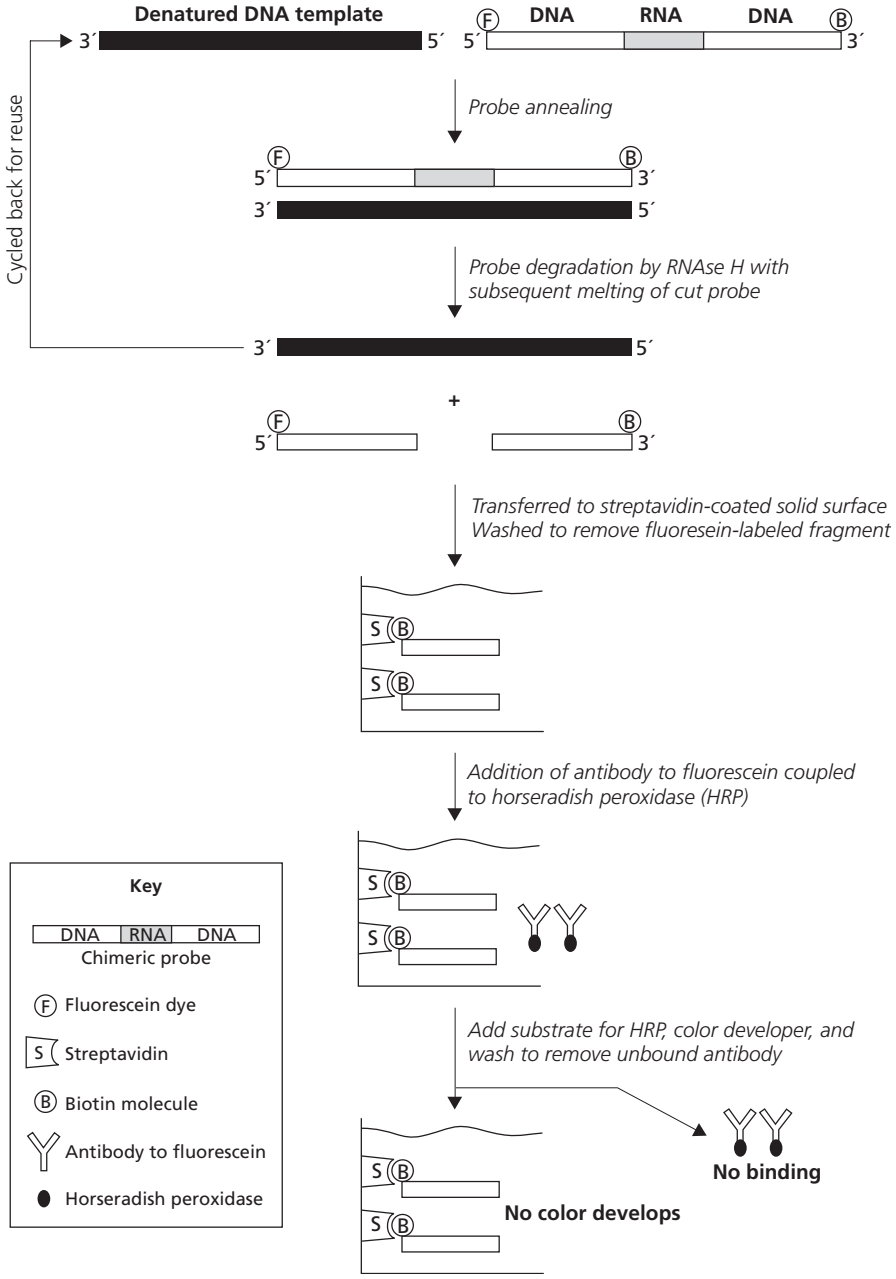

Figure 7 *Cycling probe technology (see text for details). Reprinted with permission from Wolk et al. 2001.*

pattern from the PCR reaction product. Patterns are compared with standard patterns. Kits are currently available for HCV genotyping (based on the 5′ NC region), HIV protease and reverse transcriptase mutation analysis, HBV precore promotor and precore region and polymerase mutation analysis and genotyping, and HPV genotyping.

Pyrosequencing™ (Pyrosequencing, Inc., Westborough, MA and Uppsala, Sweden) is a process by which short fragments of DNA sequence (i.e. 20–30 bases) are determined (Figure 9) (Wolk et al. 2001). With this technique, a sequencing primer is hybridized to a DNA template and incubated with DNA polymerase, ATP sulfurylase, luciferase, apyrase, adenosine 5′-phosphosulfate, and luciferin. Complementary dNTPs (dATP shown in Figure 9) are serially added to the reaction mixture. If a dNTP is incorporated into the strand, pyrophosphate is released in a quantity equal to the amount of incorporated dNTP. ATP is generated and drives a luciferase reaction so that light is generated, monitored by a charged-coupled device camera, and converted to graphic data of peaks called a pyrogram. The enzyme apyrase modifies residual dNTPs prior to incorporation of dNTPs in subsequent reactions.

MOLECULAR EPIDEMIOLOGY

A variety of molecular techniques for epidemiological strain typing are currently available. Genomic DNA restriction site analysis involves comparison of the number and sizes of DNA fragments produced by digestion of DNA with a restriction enzyme. Because of the specificity of restriction enzymes, complete digestion of an organism's genomic DNA by a specific restriction enzyme provides a reproducible array of fragments that can be separated by agarose gel electrophoresis and visualized by staining with ethidium bromide. Variations in the array of fragments generated by a specific restriction enzyme are called restriction fragment length polymorphisms (RFLP). Changes to RFLP patterns can result from gene sequence rearrangements, insertions or deletions of DNA, or base substitutions within the restriction enzyme cleavage sites. The disadvantage of this technique is that the genomic restriction fragments are usually too numerous and too closely spaced for easy analysis.

To simplify genomic DNA RFLP analysis, several techniques are available to limit the number of fragments for comparison. One approach is to probe the genomic DNA restriction fragments with labeled probes targeting multicopy nucleic acid sequences such as insertion sequences, bacteriophage DNA, or rDNA (ribotyping). The RiboPrinter® System (DuPont Qualicon, Wilmington, DE, USA) is a commercially available ribotyping system that can generate, analyze, compare, and store genetic 'fingerprint' information.

Another approach is to generate large fragments of chromosomal DNA by using 'rare cutting' restriction enzymes that recognize infrequent restriction sites and allow separation of fragments by special electrophoretic procedures. Due to shearing, intact DNA required for the generation of large DNA fragments cannot be isolated using conventional methods. Furthermore, large DNA fragments cannot be efficiently resolved by conventional agarose gel electrophoresis. Pulsed-field gel electrophoresis (PFGE) solves both of these problems. Organisms are embedded in agarose and lysed in situ,

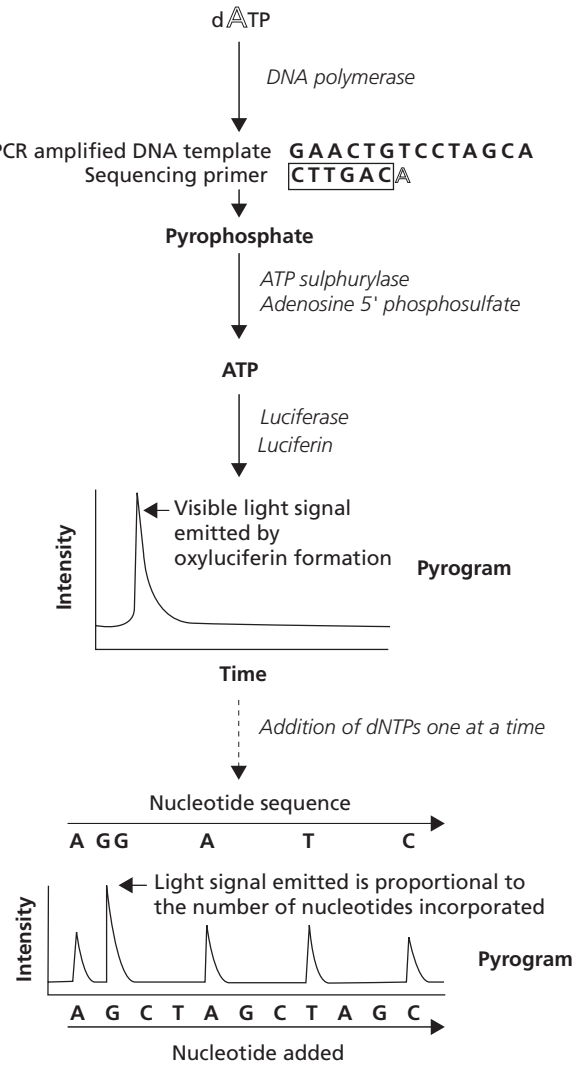

Figure 9 *Pyrosequencing (see text for details). Reprinted with permission from Wolk et al. 2001.*

and the chromosomal DNA is digested with restriction enzymes that cleave infrequently, thereby generating large (macrorestriction) restriction fragments (Wolk et al. 2001). Slices of agarose containing chromosomal DNA fragments are inserted into the wells of an agarose gel. Restriction fragments are resolved into a pattern of discrete bands on the gel by an apparatus that switches the direction of current in a predetermined 'pulsed-field' pattern, resulting in the smaller fragments migrating faster through the gel than the larger ones. The DNA restriction patterns of the isolates are then compared with one another to determine their relatedness. PFGE analysis provides a global chromosomal overview, scanning most of the chromosome, but it has only moderate sensitivity since minor genetic changes may go undetected. Interpretative guidelines for PFGE have been published (Tenover et al. 1995).

AFLP® Microbial Fingerprinting (Applied Bioscience) produces a distinctive DNA fingerprint by selective PCR amplification of restriction fragments of the entire microbial genome. The AFLP® procedure includes the preparation of an AFLP template where genomic DNA is digested with two restriction enzymes ('rare cutter' and 'frequent cutter'), which produce cohesive fragment ends and cut DNA with different frequencies. Following digestion, genomic restriction fragments are modified by ligation (joining) of synthetic, double-stranded oligonucleotide adapters with ends complementary to those of the restriction fragments. Thus, after the ligation step, genomic restriction fragments have termini of known sequences. Such an AFLP template is submitted to highly stringent PCR amplification with primers complementary to the adapter/restriction site sequences. Amplified fragments are separated by electrophoresis and visualized either directly by gel electrophoresis or by the laser detection system of an automated sequencing instrument yielding specific patterns (fingerprints). The different patterns are compared with one another to determine the relatedness of strains.

'Sequence-based' typing involves determining the sequence of portions of several microbial housekeeping genes, a procedure termed multilocus sequence typing (MLST). This technique can generate reproducible isolate profiles that can be compared against standardized databases.

MICROARRAYS

DNA microarray technology has the potential to assess and visualize thousands of nucleic acid templates (targets) simultaneously (Wolk et al. 2001). The underlining principle is nucleotide hybridization, which takes place on a 'chip,' a solid platform (e.g. glass, silica, nylon) containing genetic material (e.g. cDNA, oligonucleotides) arrayed in a predetermined fashion. When the chip is probed with cDNAs that are made from an unknown sample of RNA from a tissue or cell, complementary sequences will hybridize with various sequences already positioned on the chip. By monitoring the hybridization pattern of the unknown cDNA, the identity of the hybridized nucleic acids can be determined. The patterns can indicate which RNAs were in the tissue and therefore which genes are being expressed. Microarray technology can also be used to identify gene sequences and mutations associated with HIV-1 drug resistance (e.g. GeneChip® HIV PRT Plus Probe Array Design for analysis of subtype B protease and reverse transcriptase genes; Affymetrix, Santa Clara, CA, USA), but there is only limited support for its clinical use. Currently, a limitation of microarray technology is the high cost for instrumentation and disposable supplies. In addition, there is an inability to easily analyze the enormous amount of information potentially available through this technology.

CONCLUSIONS

Molecular diagnostic testing is revolutionizing clinical microbiology enabling testing that is faster and more sensitive than conventional methods. The field is rapidly changing as new technology evolves for specimen preparation, nucleic acid amplification, and nucleic acid sequence analysis and interpretation.

INTRODUCTION AND OVERVIEW

Bacterial immunoserology has long been an important component of the diagnosis of infectious diseases. As is so often the case in medicine, the subject is not precisely defined or confined by its title, nor is it always or necessarily underpinned by a thorough scientific understanding of the mechanisms on which it is based. Indeed, rather than immunology being the science out of which bacterial immunoserology emerged, the reverse is often more true. Empirical observations made by early bacteriologists in the pursuit of clinical diagnosis were often the platforms for subsequent scientific immunological exploration.

Bacterial immunoserology is also part of the long tradition in diagnostic microbiology, whereby parallel developments in other medical sciences have been adopted into the subject to satisfy the understandable demands of clinicians for ever more rapid results.

Bacterial immunoserology also illustrates well the need to revisit subject areas in medicine regularly in the light of technological advances. The most recent is the advent of molecular biology. To give two examples: First, the advent of recombinant antigen techniques now allows the use of antigens in amounts well beyond those naturally available, thus unlocking the ability to devise tests which were theoretically, even obviously, attractive in the past but simply impossible to deploy on any useful scale. Obvious examples include antigens not expressed extracellularly (e.g. pneumolysin in *Streptococcus pneumoniae*) or antigens from organisms never or hardly ever cultured successfully (e.g. *Treponema pallidum*). Second, the developments in proteomics, transcriptomics, and microarrays will permit a more logical and precise definition of which antigens (and in which form) might be useful for further study.

All this being so, bacterial immunoserology currently comprises a whole range of methods, often empirical, occasionally paradoxical, but above all practical, deployed to aid in the diagnosis of infectious diseases.

The subject can be divided into two clear areas. First, aiding diagnosis by measuring the response of the patient (or patients), for instance by finding antibodies to a particular organism or its products. Second, by using immunological reagents (usually produced by animals or from another nonhuman source) to detect organisms or their products. These two approaches will be considered separately.

First, however, it is necessary, briefly, to consider the various responses that bacterial invasion evokes. Detailed and comprehensive accounts of the many components of the immune response are found elsewhere in these volumes. What follows is a greatly simplified overview, suitable only for the present purpose.

THE MULTILAYERED RESPONSE TO INFECTION

The immunology of infection is frequently portrayed as a battle in which the aggressors (microbes) gain footholds in the body by overcoming the standing defenses, such as skin, mucous membranes, etc., and then begin to multiply, spreading further, creating more local damage. At the same time, a wide range of microbial products (enzymes, toxins, etc.) are released, which may enter the circulation and cause damage at sites distant from the portal of entry. The body responds in diverse ways, each designed to limit the damage, localize the extent of invasion, and, where necessary, neutralize the toxicity of elaborated bacterial products. Outcomes range from resolution (implying a return to total normality, as though no infection had ever occurred, as for instance in pneumococcal pneumonia) through varying degrees of residual damage (with consequent morbidity) to death.

There is an order and a chronology to these events, which allows bacterial immunoserology to be applied.

THE ACUTE-PHASE RESPONSE

The acute-phase response (APR) is the body's generic response to any significant injury, but its magnitude is greatly enhanced if infection is involved or supervenes. There are three pathological components: the development of local hyperemia as blood vessels dilate, the local exudation of certain plasma proteins, and the attraction and diapedesis of white blood cells (predominantly neutrophils) into the tissues at the site of damage. This is not a passive process. Indeed, it is the consequential responses of the body in augmenting the white cell response and the plasma protein response that make the APR a valuable phenomenon in the diagnosis of bacterial infections.

As neutrophils are attracted to the site and consumed, the bone-marrow neutrophil reserves are immediately released into the circulation and the bone-marrow stem cells respond by producing more neutrophils. This results in a peripheral leukocytosis with a pronounced neutrophilia, containing predominantly juvenile neutrophils, the so-called 'shift to the left.' In inflammation due to infection, these events are considerably exaggerated, probably due to the ability of most bacteria to degrade complement (a prominent acute-phase protein), the degraded or 'split' products of which are an extremely powerful chemotactic stimulus for neutrophils.

Within 2–4 h of injury/infection, the liver begins to synthesize and release large amounts of a range of plasma proteins (acute-phase proteins), some of which are normally found in the plasma in small amounts (e.g. complement) and some of which only appear under these circumstances, e.g. C reactive protein (CRP). The magnitude of this response (i.e. the levels of these easily measured proteins) gives an index of the degree and extent of the inflammatory damage being undergone by the body, from which inferences can be drawn. Thus, an apparently inappropriately large APR response (for instance, a very high white blood cell count, a very pronounced neutrophilia, and a very high CRP level) would imply that either a noninfective injury was much larger or more severe than originally suspected, for instance having gone on to necrosis, or, commonly, that infection was present.

The ease and speed with which both the leukocytosis and CRP can be measured and their equally rapid response to successful control of the APR, for instance by correct chemotherapy of an infection, make them useful and versatile tools in clinical microbiology. They are especially useful when the patient has not responded as well as expected to antibiotic therapy, say by continuing to be febrile. There being many other reasons for the fever, a normal or rapidly declining leukocytosis and CRP might eliminate lack of control of the infection as the reason. Conversely, if both remained high, it might be wise to alter therapy, take further samples, or even to contemplate superinfection with a different organism.

A major disadvantage of the APR is that it is nonspecific, i.e. the organism is not identified, or not, at any rate, by this means. However, the APR can be very specific indeed in a negative sense. Thus, if an organism is isolated from a blood culture or another pathologically very significant site, such as cerebrospinal fluid, it will be very unusual indeed if all parameters of the APR, and particularly the peripheral white blood cell count (WBC) and the CRP, are entirely normal.

This very combination of events occurred many times several years ago, when the organism *Stenotrophomonas maltophilia* (then called *Psedudomonas maltophilia*) was isolated from blood cultures in apparently well, or at least apparently nonsepticemic, patients. The clearly negative APR parameters led to a search for another explanation and it emerged that blood culture samples were being cross-contaminated with *Ps. maltophilia* from nonsterile biochemistry sample tubes, filled at the same venepuncture. The condition dubbed 'pseudobacteremia' was thus identified (Jumaa and Chattopadhay 1994). Similar intelligent uses of the APR have undoubtedly saved many patients from unnecessary antibiotic therapy.

Problems in interpretation of the APR

Problems may be encountered with interpreting the APR under several circumstances.

First, if either of the major contributing organ systems is grossly deranged, then production of the APR components may be inappropriately low or even absent. Thus, the WBC response may be abnormally low in marrow

failure. Acute-phase proteins may not be produced in normal amounts in patients with liver disease, whether acute or chronic. Rare conditions in which complement or its components are not manufactured may greatly dampen the amplitude of the APR.

Second, there are rare instances in which organisms, especially *Staphylococcus aureus*, can survive often for many years, in a 'privileged site,' immured from the APR. A good example is the so-called Brodie's abscess (Stephens and McAuley 1988) in which the infection survives as an indolent localized pocket of infection in a sclerosed area of bone, often the residue of a childhood bacteremia that did not progress to acute osteomyelitis. After a period the APR declines, although the CRP is often not entirely normal. However, the patient very occasionally has a febrile attack or even a rigor. If blood cultures are taken, they may be positive. Brodie's abscesses are easily seen on X-rays. The erythrocyte sedimentation rate (ESR) is often raised, but this is as a result of the dysglobulinemia and secondary anemia (often called the 'anemia of inflammation') due to longstanding production of humoral antibody (see below), rather than the presence of any acute-phase protein.

Third, in severe infection due to gram-negative bacilli, such as *Escherichia coli*, the WBC may fall precipitately rather than rise. This effect is thought to be due to the direct effect of endotoxin (lipolysaccharide (LPS)) on the neutrophils, causing their degranulation and resulting in some of the features of disseminated intravascular coagulation (DIC). Prompt and effective therapy of the presumptive gram-negative septicemia will often result in a rapid and gratifying resolution of the leukopenia.

Recent developments in measuring the acute-phase response

There has been a longstanding wish to find a component within the APR that is specific to infection and, therefore, will allow the distinction to be made between noninfective inflammation and sepsis without recourse to the subjective estimates of magnitude alone. In any case, it is frequently the case that infective and noninfective values overlap. This desire is particularly strong in those caring for infants and children (Nuntnarumit et al. 2002) and those dealing with intensive care patients of any age, in all of whom physical signs are notoriously unreliable. There have been two lines of investigation.

First, several candidate acute-phase proteins have been put forward as being disproportionately raised or even raised at all in bacterial infection. The most recent candidate is procalcitonin (PCT). The evaluation of PCT has parallelled that of many other candidates over the years, in that it seems that PCT does indeed rise higher in bacterial inflammation than in noninfective syndromes (or viral infection), but still not exclusively so (Balc et al. 2003; Schuttrumpf et al. 2003).

Second, it is known that one component of the APR does behave very differently in infection. This is the neutrophil. When neutrophils phagocytose a live bacterial cell, they must first kill the bacterium prior to being able to digest it. The intracellular killing is achieved by a respiratory energy burst fuelling an oxidative microbicidal system, which results in the organism being killed by halides (probably by iodination). This efficient system will kill *S. aureus* within approximately 20 min (Klebanoff 1980).

It is possible microscopically to identify such 'activated neutrophils' by supravital staining methods wherein tetrazolium (for instance, nitroblue tetrazolium (NBT)) salts are reduced to insoluble formazan, which is visible as a deposit in the neutrohil phagosome. It was, therefore, hoped that estimation of the percentage of peripheral blood neutrophils reducing NBT would be much higher in patients with severe infection. In general, this is so, but extensive evaluation concluded that, once again, the test was not specific enough for the purpose, although it retains an important place in the testing of neutrophil function (see below). Attempts to find an 'infection-specific' component of the APR will doubtless continue. The prize is immense.

Final comments on the APR

Clinicians and microbiologists evaluate the APR in most patients daily without formally recognizing the exercise. The mundane nature of the APR is, in fact, one of its most important aspects. The ability rapidly to detect inflammatory damage, including that due to, or complicated by, bacterial invasion, rapidly to deploy an effective systemic response to the site that can begin to impede the progress of the damage and moreover deliver effector cells that can kill pathogenic bacteria and scavenge debris, is a triumph of evolution. This mechanism deals, mostly successfully, with the vast majority of infective assaults on the human body. Its manifestations range from small pustules on the skin to large areas of suppuration, such as peritonitis. Studies of neutrophil function and of other aspects of the APR suggest that low-level ongoing activity of this system, outside the occasions when it is recognizably evoked, is probably essential to the maintenance of the integrity of mucosal surfaces and the skin. The development of 'mucositis' in patients in whom neutrophil function or numbers is depleted also suggests this.

If the APR is successful, invading organisms do not, largely, survive to present an ongoing threat and, hence, do not require further response. There are, however, organisms that survive the APR.

THE GRANULOMATOUS RESPONSE

In an immunocompetent host, the granulomatous response is the exception rather than the rule and is induced by organisms that can survive intracellularly. Thus, *Mycobacterium tuberculosis*, *Listeria monocytogenes*, and *Brucella* spp. will be the organisms predominantly involved in temperate countries. Other species will be more common in other climates and environments.

The unity of the above hypothesis is strikingly supported by the occasional example of what happens when immune defects in, for instance, the neutrophil bactericidal mechanisms, detected by a demonstrable inability to reduce NBT, even in the presence of live bacteria, force the body to react to unkilled common organisms, such as staphylococci, as though they were intracellular bacteria, such as mycobacteria. This results in granulomatous reactions to these mundane bacteria and produces a clinical disease called chronic granulomatous disease (CGD) (Gallin and Fauci 1983). CGD was for some time thought to be an atypical form of tuberculosis, but the discovery of the intracellular killing system and of defects within it showed that affected children were forced to deal with all bacteria in a way in which their healthy peers reserved for rarities. Other examples of deficits, such as myeloperoxidase deficiency, and so on, serve to emphasize the pivotal importance of the neutrophil bactericidal pathway in determining how the body reacts to bacteria.

There are two consequences of the granulomatous response relevant to bacterial immunoserology.

First, the surviving organisms will enter the active specific immunity system, antigen will be processed, and both cellular immunity and humoral immunity will result. Thus, it will be possible to devise tests based on (1) humoral antibody detection and/or (2) evocation of specific cellular immune responses to antigens to diagnose infection with these organisms.

Second, it is highly possible that the bacteria involved will remain alive within the body, albeit localized and contained by the granulomatous reaction. Frequently, it seems, these contained organisms adopt a different physiological and metabolic state, and this may even extend in some species to a viable but noncultivable state. In terms of the infection or disease associated with the organism, it is often described as a latent phase. Latent infections may and do reactivate, often when an intercurrent illness, medical procedure, acquired immunoincompetence, or simply advancing age depresses the immune system below the level required for continued containment of the organism. Thus, it will be possible not only to devise tests based upon (1) humoral antibody detection and/or (2) evocation of specific cellular immune responses to diagnose infection with these organisms, but also, under certain circumstances, to identify latently infected but seemingly healthy individuals who will be at risk of subsequent symptomatic disease. Pre-emptive therapy may therefore be possible.

Humoral antibody production

Figure 1 is a diagrammatic and idealized depiction of humoral antibody production after the introduction of pathogenic bacteria into the body, subsequent bacterial infection, and development of active acquired immunity in a patient never before exposed to this particular organism.

All specimens for serological studies must be seen as individual static 'snapshots' in a dynamic process, the natural history of the disease. This is easier to appreciate in virology since viral diseases have, until recently, run

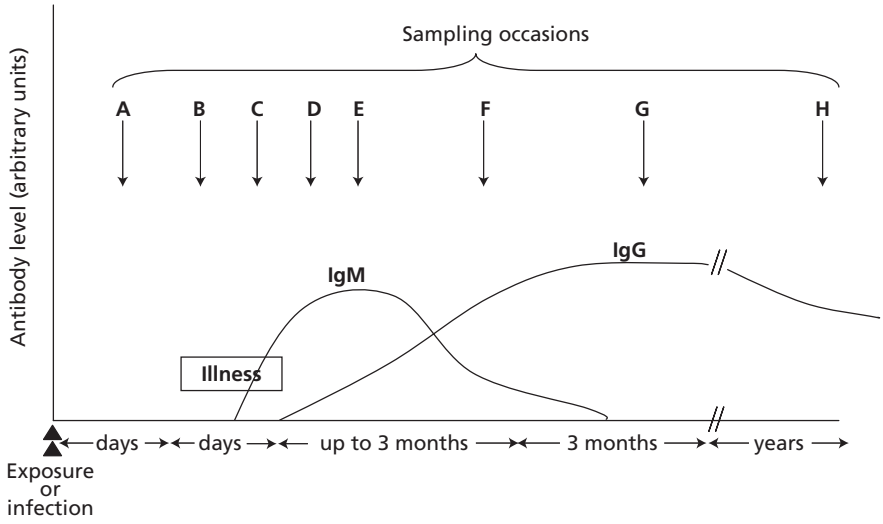

Figure 1 *Schematic representation of humoral antibody response following a single point exposure to an intracellular infectious agent.*

their course, there being no possibility of intervention. Nonetheless, the same view of many nonpyogenic, granulomatous bacterial diseases is equally important.

Before considering the differing significance of results from specimens taken at the sampling occasions given in Figure 1, it is important to clarify two matters of simple practical importance.

First, this account will shortly be referring to antibody 'titers,' a measure of the amount of antibody/unit volume determined by serial dilution (titration) of a sample to the endpoint of reactivity. These will be referred to as, for example, 'a titer of 1 in 32 (or 1/32).' This is a scientifically incorrect statement that has become correct by common usage. Strictly, titers are the *reciprocal* of serum dilutions, so the preceding should be 'a titer of 32,' the titer being a measure of the strength of the reaction studied, in this case 32 units/volume. It is a way of comparing the amounts of antibody in two or more different samples. This is an essential concept in the quest to study and compare serial samples, but it can be confusing. Despite many laudable efforts to correct this problem, it persists. To summarize, a sample with a titer of 1/32 has a stronger reaction (i.e. contains more antibody/unit volume) than one with a titer of 1/8.

Second, the technical reproducibility of doubling dilution is one dilution either side of the intended value. Hence, a serum with a titer of 1/32 may, some of the time give a titer of 1/64 and some of the time 1/16. In order, therefore, to be certain that two titers are significantly different, it is insisted that they differ by at least two dilutions. This leads to the stipulation that a significant rise in antibody titer between two samples must be at least four-fold, say 1/8 to 1/32, or 1/10 to 1/40.

Figure 1 shows that after infection, there is often a short period in which the patient remains ostensibly unaffected and well (the incubation period). Next follows the clinical illness, during which it is often possible to directly detect the causative agent and so make the diagnosis without recourse to bacterial immunoserology. However, if it is assumed that the organism cannot be cultured, or that inadvertent antibiotic therapy has rendered culture useless, or for any other reason diagnosis cannot be made by direct detection, bacterial immunoserology may be useful.

It is, therefore, important to note that IgM is the first antibody produced by the host, often whilst the clinical illness is still ongoing. IgM is the classical first response and, because of its large molecular size, remains confined to the bloodstream even after its production declines. It can usually be detected for at least 3 months after its first appearance. Unfortunately, however, IgM is a notoriously difficult immunoglobulin with which to contend in assays, mainly because it is so avid or 'sticky' that it frequently reacts with antigens other than that which evoked it. Nonetheless, its appearance (and, therefore, detection) strongly suggests both a first infection with the appropriate organism and its recency.

Shortly thereafter, specific IgG becomes detectable. IgG is a much more easily assayed immunoglobulin and assays based upon it are usually very specific. However, its later appearance and the fact that it is the 'memory' immunoglobulin (i.e. the antibody that persists for years, perhaps for life) make its detection difficult to interpret in a single specimen. To settle a judgment of de novo production (and, therefore, recency) on IgG levels requires evidence of increasing levels over a short period of time. This is the classical immunoserological concept of the rising titer.

Some recent work has drawn attention to the differences in avidity for the same antigen between the IgG produced for the first time and that produced later or after rechallenge with the same antigen. These differences can be demonstrated in technically simple ways. It may, therefore, be possible to devise IgG assays that will also indicate recency of infection. However, although this interesting approach has been pursued in a small number of instances (Prince and Leber 2002), it has not yet gained wide support.

Turning, therefore, to the details in Figure 1, it is now possible to discuss the results of assays for both IgM and IgG at the different sampling occasions and to interpret the significance of the results. It will already be evident that the same assay result (especially for IgG) may have an entirely different significance, depending on when it was taken in relation to the disease.

SAMPLE A

No antibody of any sort is detected. Absence of antibody in the incubation period is to be expected, implying that if known to have been exposed, the patient is likely to become ill soon. This is not often a useful observation in bacterial infection, but it is of immense use in the childhood viral exanthema, allowing isolation.

SAMPLE B

Early in the illness and no antibody is yet detectable. Although such samples will hardly ever themselves make a diagnosis, such so-called 'baseline' or 'acute' samples are vital for subsequent comparative tests (see below). Many experienced investigators simply store such samples until later samples are obtained.

SAMPLE C

In later illness, specific IgM is detected. Provided that the specificity of the assay is beyond question, the diagnosis can be made, the presence of specific IgM being evidence of both a novel antibody and of a recently produced antibody. However, further samples should be requested to confirm subsequent IgG production so that specificity is confirmed (see below).

SAMPLE D

In late illness or early convalescence, both IgM and IgG are detected, the specificity of the IgG complementing and confirming the implications of the IgM result. This is a common format for commercial test kits. However, the IgG levels found at this stage may border on the limits of detectability.

SAMPLE E

In established convalescence, IgM can still be detected and IgG is plentiful. It is also now possible to explore an alternative and highly specific way to make the diagnosis. If it can be shown between successive samples that the levels of IgG are significantly increasing with time, this is good evidence that the infection is ongoing or recent. Thus, if the IgG antibody level is greater in E than in D, this will be so and will secure the diagnosis. It will be even more certain if E is compared with B, since B contains no antibody. Hence, the prudence in taking samples early in the illness, though they alone cannot make the diagnosis (see above).

It might be argued that samples taken prior to A might also serve. For instance, serum may be available from an unrelated event in previous years. However, all that can then be said is that the infection has occurred some time between the sample dates of 'pre-A' and E. If this is a long time (months or even years), the significance might be lost in terms of any one specific episode of illness if several have occurred in the interval.

SAMPLES F AND G

IgM is declining to low levels and its index of recency is becoming eroded. Low levels of IgM antibodies (and IgM-like antibodies) can be found in normal states. However, the relatively high levels of specific IgG make recent infection likely, but unless earlier samples are available for comparison, the results on a single sample taken at F might be misleading. Since IgG production is now nearly maximal, comparison of the titer at F with that at G may not help. It might be observed that the need to make the diagnosis is now long past and, therefore, the exercise is pointless. However, it is occasionally very important to establish the nature of an illness undergone several months before, perhaps in a distant location, to ascertain the need to test contacts and to gauge prognosis and the need for further, perhaps invasive, investigations. In earlier days, a common such example was enteric fever.

The serological picture has now gone full circle because similar questions can now be asked as were also asked at point A, although the answers will be quite the opposite. If antibody is detectable during the incubation period, the patient is immune, assuming the antibody detected correlates with protection. It is remarkable how often a previous serum specimen, often submitted for a totally unrelated reason, such as, for instance, antenatal screening, can be recalled and tested to solve a current problem. Consequently, storage of sera is good practice.

SEROEPIDEMIOLOGY

A very important aspect of humoral antibody testing is the use of the results from individual patients being viewed collectively as those of a population. This is the basis of the very important subject of seroepidemiology, whereby antibody testing of carefully structured populations is designed to address specific questions in relation to the incidence and prevalence of a given illness within the population. Good evidence can be produced to assess the extent of disease, those groups most likely to contract it, and, therefore, those groups most likely to benefit from interventions such as vaccination. This is yet another reason for sera to be stored over a longer period. If storage of all sera is impracticable, the preservation of a collection representative of the wider population and extending through a period of several years is a useful surrogate and will greatly inform epidemiology studies.

Three other points require to be addressed before progressing to look at the application of these principles in real examples.

First, in disease the antigen persists. The situation is not precisely analogous to the single antigen injection given under experimental conditions on which Figure 1 is based. Patients may receive both primary and further 'doses' of antigen as the illness continues. Therefore, the speed and magnitude of antibody production will be greater than in experimental observations.

Second, in clinical disease the host is required to respond to a variety of antigens of differing immunogenicity, both polysaccharides and proteins. A spectrum of antibodies results, each directed against a different antigen. These different antibodies may exhibit markedly different degrees of persistence, some being detectable for years, others for only a few months, perhaps reflecting the different immunogenicities of the antigens which elicited them. Whatever the explanation, these phenomena can be exploited to good practical effect in bacterial immunoserology, an excellent example being the contrasts between the O and H antibodies in enteric fever (see below). A side issue of this point is the realization that antibodies evoked by weak (poor) or incomplete immunogens may not only be transient in their appearance in the circulation but also may escape immunological memory and be re-evoked in subsequent infective episodes.

Third, there is little true knowledge of the functions of the many antibodies which can be detected. The point re-emerges that bacterial immunoserology is an empirical, albeit useful, practice. What follows are several examples of the practical application of humoral antibody testing in diagnostic bacteriology.

Enteric fever (infection with *Salmonella* Typhi) is here used as the paradigm. Infections with *Ss. paratyphi A*, *B*, and *C* behave similarly but are omitted for clarity.

S. Typhi exhibits three well-studied antigens. H, or flagellar, antigens, are protein in nature and unique to *S.* Typhi; O, or somatic, antigens, are polysaccharides and more widely distributed within the *Salmonella* species than in *S.* Typhi alone. The Vi, or virulence, antigen is thought to be capsular in nature and is found only in recently isolated strains.

It is relatively straightforward to produce suspensions of *S.* Typhi that exhibit either only H or only O antigens at a time (the details are unnecessary). Since these suspensions will be particulate, antibody can be detected by demonstrating the ability of the serum to agglutinate the suspension (see below). The test to be described (and many variations on this theme) is often called the Widal reaction.

Typhoid fever follows the ingestion of the organism and has an asymptomatic incubation period of 7–10 days, during which the organisms multiply within the gut lymphoid tissues (Peyer's patches) and subsequently invade the bloodstream to give rise to a particularly serious form of gram-negative septicemia, often characterized by a leukopenia. Before ingestion of *S.* Typhi and during the incubation period, no antibodies will be detectable. As the fever breaks, diarrhea ensues and at this time, or shortly afterwards, both O and H antibodies may be detectable. As the disease continues and, hopefully, thereafter subsides, both antibodies can be detected, although typically O antibody may be more plentiful than H. In late convalescence the H titer continues to rise, but the O titer plateaus. A year later, the H antibody will remain easily detected, but O antibody may have become undetectable once more.

The preceding commentary serves to explain these results. O antibodies rise first but, more importantly, decline quickly after the illness, perhaps because of their nonprotein nature. Though less specific than H antibodies they serve as a good index of recency. Their specificity, however, must be confirmed by the copresence of the highly specific H antibodies, which also serve as the memory antibody in future years, when O antibody is gone. Four-fold or greater rises in antibody titers in either antibody indicate ongoing production. Thus, it is possible to distinguish between a nontyphoidal enteritis, early typhoid fever, recent typhoid fever, and past typhoid fever. No IgM detection was typically employed in the Widal reaction, although it might well have been in the same way as that for the brucella test (see below).

Vaccination against typhoid (and paratyphoid) fever has been commonly practiced since the days of Almroth Wright. Most such vaccines were intended to evoke H antibody, which is at least partially protective. However, such antibodies can confuse the interpretation of the Widal reaction, but in cases of doubt antibodies to the Vi antigen can be sought. This antigen was traditionally excluded from the vaccine but is present in great amounts in a natural and ongoing infection.

The Widal reaction has fallen from favor for three reasons. Modern cultural and noncultural detection methods make it increasingly outmoded, vaccine changes make it increasingly difficult to interpret, and, most of all, the development of antibiotics capable of being used widely and effectively (especially fluoroquinolones) limits the necessity to make serological and retrospective diagnoses.

BRUCELLOSIS

Brucellosis is a zoonosis. Humans at risk include farm workers, vets, slaughter men, and those in other occupations concerned with livestock and farms. The organism can also be transmitted via the ingestion of unpasteurized milk.

Brucellosis is a disease with discernible clinical stages. It begins with an acute bacteremic phase in which the patient has chills and rigors, is usually severely debilitated, and sometimes has a rash. This phase may then remit and then recur. Sometimes this cycle is repeated several times, the characteristic temperature pattern earning the disease its alternative name of undulant fever. Brucella organisms can usually be isolated from the blood at this stage but successful culture of this very fastidious bacterium is very difficult and cultures are often pronounced negative. Additionally, culture is often discouraged because of a high risk of laboratory-acquired infection. Untreated, the acute phase eventually peters out and the organisms localize into the reticuloendothelial system, principally into the liver and the spleen, together with involvement of bones and joints, especially of the spine. Unsurprisingly, as the infection becomes chronic, the patient becomes debilitated with anemia, low-grade fever, weight loss, and increasing problems with arthritis, especially of the spine. If still unsuspected the disease continues, eventually shortening the life span and occasionally ending in brucella endocarditis.

The difficulties in culturing the organisms make the diagnosis of brucellosis an ideal opportunity for bacterial immunoserology, and it is a particularly instructive example. The main technique used is that of agglutination of whole brucella organisms. Serum taken in the acute phase will contain high levels of specific agglutinins, and this result will of itself strongly suggest the diagnosis of acute brucellosis, the antibody being unusual in the general population. Since at this stage the organism is predominantly in the blood, it also follows that the agglutinins will be largely of IgM. IgM is a pentameric immunoglobulin rich in disulfide bonds, and exposure to 2-mercaptoethanol (2ME) destroys its activity. If, therefore the agglutination test is performed in parallel, first using normal saline as diluent and

second using saline plus 2ME, a substantial drop in the agglutination titer in the second test strongly suggests that the agglutinins are IgM in nature and confirms that the patient has acute brucellosis. This is doubly important since the disease responds better and more completely to antibiotic treatment in the acute phase.

As the disease (if undiagnosed and untreated) enters the chronic phase, the titer of agglutinins will fall, but not usually to an undetectable level. However, faced with a patient with a suggestive clinical picture but only very modest levels of antibody in the agglutination test, the diagnosis may be difficult to sustain by this means alone. Brucella organisms (or, perhaps more accurately, processed brucella antigens in the tissues) evoke IgG antibodies in high titers, which react in a complement-fixation test (CFT). Thus, the detection of low-titer agglutinins, the activity of which is not abolished by mercaptoethanol, and a strong reaction to high titer in the brucella CFT is the classical immunoserology of chronic brucellosis, a condition requiring very prolonged antibiotic therapy with drugs that will penetrate granulomata and one that is difficult to declare cured even after many years. Thus, bacterial immunoserology can not only diagnose but also stage the disease and, thereby, give useful guidance to therapy and cure.

There is one caveat. As will be seen below, it is a characteristic of intracellular infection that both cellular immunity and hypersensitivity will be evoked, especially in the chronic phase. Repeated exposure to brucella antigens can result in such hypersensitivity without the necessity of preceding infection with the organism. This can be manifest as a positive 'Brucellin' skin test, which is performed and read in a way analogous to the Mantoux test in tuberculosis (see below). Low levels of agglutinins can accompany this, although the typically negative brucella CFT will suggest an absence of genuine chronic infection. The hypersensitivity nature of the phenomenon can be positively shown by the detection of specific IgA in the serum.

Thankfully, acute brucellosis is now a rare human disease in most advanced countries due to the eradication of the infection in animals by a slaughter and restocking approach. However, patients with chronic brucellosis will continue to be discovered for some time to come. In many laboratories, a single screening test using an enzyme immunoassay technique (see below) is now used.

SYPHILIS

The history of the serological diagnosis of this medically and socially very important disease is almost the history of bacterial immunoserology in microcosm. The protean clinical manifestations of syphilis, resulting in its nickname of the 'Great Imitator,' made the need for an objective and impartial laboratory test essential for differential diagnosis in illness and for the detection of a latent phase of indeterminate duration (up to decades).

The first tests were based on the empirical observation that a liver extract from syphilitic fetal liver appeared to fix complement in the presence of sera from patients with syphilis. The obvious, but erroneous, assumption was that antigens from the then (and still) uncultivable *Treponema pallidum* were the basis of the test, subsequently universally dubbed the Wassermann reaction (WR). In fact, even some of the early observations hinted at two anomalies with the WR. These were the finding of false-positive results (reactors who clearly did not have syphilis) and occasional claims that the test worked almost as well if nonsyphilitic tissue was used as the antigen. Finally, it emerged that the relevant antigen (called cardiolipin) could be found in other normal tissues and was eventually able to be synthesized. It also emerged that the substance reacting with cardiolipin was not, in fact, a true antibody but a serum component evoked, possibly due to tissue damage, in syphilis and some other states and called reagin. (Note: this substance must be clearly distinguished from the reaginic antibodies encountered in allergic states.)

Reagin is nowadays detected by a slide or tube flocculation technique (this latter being a virtually unique serological appearance in which 'agglutination' of a much coarser than normal nature is produced) using a cardiolipin preparation produced to a standard defined by the Venereal Disease Research Laboratories (VDRL) several years ago. This test is inevitably referred to as the 'VDRL test' or, simply, the VDRL.

As experience grew with cardiolipin tests, it became obvious that specificity was a major problem and that false-positives were common. These so-called biological false-positives (BFP) were of two sorts. Many were transient and, interestingly, often associated with diseases or states in which liver function was temporarily deranged. Common examples included viral hepatitis, glandular fever, and pregnancy. When the associated condition resolved, these acute BFPs became negative. A timeframe of 3 months usually sufficed for this. Conversely, chronic BFPs by definition of more than 3 months' duration were frequently associated with much more serious and chronic diseases, typically of the autoimmune variety, such as systemic lupus erythematosus (SLE).

Nonetheless, the VDRL was also still positive in almost all cases of syphilis and retained and still retains its place in the diagnosis and management of the disease because the VDRL titer is an extremely useful index of the activity of syphilis. It has been justifiably called 'the ESR of syphilis.' Its retention, however, made mandatory the devising of other much more specific tests to set the VDRL result in a proper context.

First efforts centered on attempts to grow *T. pallidum* and thereby prepare a highly specific antigen for (at that time) the inevitable CFT. An early partial success was the isolation of what came to be called Reiter's strain. This is not *T. pallidum* but at least the extracted antigen (Reiter protein) was more specific than cardiolipin and

conferred a treponemal group status to any antibody detected. This was the basis of the Reiter protein CFT (RPCFT).

Although *T. pallidum* was, and yet remains, uncultivable, the organism can be made to infect and multiply within rabbit testes and on this basis artificial serial passage can be accomplished. The resultant suspensions of live *T. pallidum* so produced were used in a form of neutralization test, whereby the characteristic motility of these live spirochetes was shown under dark ground microscopy to be inhibited by the presence of immune serum. This very laborious and expensive assay was the *Treponema pallidum* immobilization (TPI) test. Immunological technical developments have since allowed the *T. pallidum* suspension to be used as the basis of an indirect immunofluorescent test (fluorescent treponemal antibody (FTA) test). An even more specific version of this approach was then devised, whereby treponemal group antibodies were removed from the sample, prior to testing, by adsorption with the Reiter protein antigen so that any remaining antibodies must be to antigens found on *T. pallidum* only. This is the principle of the FTA (abs) test. *T. pallidum* material was also made to adhere to red cells, allowing the development of a passive hemagglutination test (the TPHA).

In terms of *T. pallidum*-specific tests, it is now possible, using genomics, proteomics, and recombinant antigen technology, to produce a range of tests, utilizing a range of different formats (most commonly enzyme immunoassay assay (EIA)), which detect antibodies specific to only a few epitopes of *T. pallidum*. As will be appreciated, many of these kit-based tests will also be capable of being made specific for IgM antibodies, if needed. Thus, over 100 years of immunoserological development has furnished the tools to decipher the diagnosis of syphilis, but it is testimony to the practicality of the bacterial immunoserology approach that the oldest, least specific test and one that in retrospect never detected an antibody at all, the VDRL, is still an essential component of the syphilis testing portfolio.

Tests of hypersensitivity and cellular immunity

In intracellular infections, a range of immunological phenomena occurs in addition to the production of humoral antibodies. The granulomatous nature of the histological response has been mentioned already. Two further characteristics can also be capitalized upon to devise diagnostic tests. These are the behavior of lymphocytes and other cells in response to an appropriate antigen and the development of hypersensitivity phenomena.

Other chapters will discuss these matters in detail. As always in bacterial immunoserology, this section will concentrate on the practical applications. This account will deal almost exclusively with tests in tuberculosis, which is currently by far the major disease in which these tests are used. Hypersensitivity tests were the first to be developed.

HYPERSENSITIVITY

The fundamentally different immunological processes involved in tuberculosis, the archetypal model of cell-mediated immunity, were recognized from the outset. Koch and other early workers were able to show that primary infection with *M. tuberculosis* could be shown to have occurred by the alteration in the body's response to intradermal injection of a protein extract of the organism (originally, Koch's old tuberculin; later purified protein derivative (PPD)). Before infection, no reaction occurred, whereas after infection, an area of redness and induration within the skin appeared 72 h after injection. It was also noticed that reinfection with *M. tuberculosis* in animals with a positive skin test provoked a brisk, even necrotic, reaction at the site of reinfection (Koch's phenomenon), again indicating that the body's reaction to the organisms was altered forever. The intradermal test was later standardized and done by differing techniques (Mantoux test, Heaf test), all of which can variously be described as tuberculin skin tests (TST).

It is important to note that this 'tuberculin conversion,' i.e. the acquisition of hypersensitivity to tuberculoproteins, occurs whether or not the primary TB infection progresses to manifest clinical illness (progressive primary tuberculosis, including tuberculous meningitis and miliary tuberculosis). If conversion occurs and the subject remains healthy, including nowadays no radiological evidence of disease, the supposition is that the subject has latent TB infection (LTBI). The clinical significance of these different outcomes and the results of reactivation of LTBI to produce 'adult-type' tuberculosis in later life are found elsewhere in these volumes. From the bacterial immunoserology viewpoint, the significance is that TSTs can act as a quasi-serological marker that infection has occurred.

It is remarkable that a test devised in the nineteenth century is still in daily use in the twenty-first century. It is also testimony to the dearth of any better methods for the diagnosis of primary tuberculosis. It should be remembered that over 90 percent of cases of primary tuberculosis are asymptomatic and that in symptomatic primary disease the bacillary load in the body is so small that even the most sensitive of modern cultural techniques are usually unhelpful.

TSTs were the only method until very recently, but there are considerable problems with them. First, they are cumbersome to perform, require an injection (particularly unpopular with children, the most tested group), require a second visit for the 'reading,' and are subjective. Second, infection due to nontuberculous

mycobacteria, such as *M. avium-intracellulare*, *M. malmoense*, and other environmental species, especially in childhood, can also elicit positive TSTs. Third, BCG vaccination, which is, after all, an artificial primary mycobacterial infection, will also give positive TSTs, rendering the TST approach virtually useless for the detection of primary tuberculosis in a universally vaccinated population after the age of screening. Fourth, since the TST itself introduces the test antigen to the immune system, regular and repeated TSTs can produce false-positive results, the so-called 'booster effect.' Lastly, whereas it was at one time thought and, indeed, observed that once TST conversion has occurred (including by BCG vaccination) the TST would be positive for life, it is now thought that in low-incidence countries, the lack of repetitive contact with the disease allows hypersensitivity to fade. Hypersensitivity ceases, thereby, to be a reliable surrogate for cell-mediated immunity, itself a marker of past primary infection. Nonetheless, despite these many drawbacks, TSTs have proved very helpful in investigating, diagnosing and controlling tuberculosis.

EVOKED GAMMA INTERFERON ASSAYS

It is against this background that a new approach to the 'serodiagnosis' of primary infection with *M. tuberculosis* has been adopted. The new method makes use of the fact that the 'sensitized' or primed T cells, especially those of certain subsets, will produce and release gamma interferon in the presence of the appropriate antigen. The production of gamma interferon can then be assayed or otherwise detected and thus confirm or deny the previous exposure to the antigen.

Unfortunately, the composition and comparative composition of mycobacterial cell walls is ill understood. Consequently, although these evoked gamma interferon assays (EGIA) can more precisely, reliably, and objectively assess responses to tuberculin and, moreover, do so without injection and at a single patient visit and be endlessly repeated without affecting the test result, differentiation between TB and infections due to nontuberculous mycobacterial species is difficult. A common approach is to expose the cells to a range of 'tuberculins' from different mycobacteria and allocate species specificity to that eliciting the highest response.

The most desirable goal is to differentiate between responses due to BCG and other members of the *M. tuberculosis* complex. Fortunately, it is known that the molecular hallmark of BCG is the lack of the RD1 region in its genome. It is likely, therefore, that if proteins coded for by this region (for instance, early secretory antigen type 6 (ESAT6)) elicit a gamma interferon response, then the primary exposure was to *M. tuberculosis* or *M. bovis* and not to BCG (Pollock et al. 2001).

Extensive studies have shown excellent correlation between TSTs and at least one EGIA (Mazurek et al. 2001) and assessments of the later *M. tuberculosis*-specific EGIAs are under way. Assays based on this technology will benefit many patients with LTBI and others. They may, in fact, be the key to the eradication of tuberculosis rather than its control (Institute of Medicine 2002).

As will be clear from the earlier section on the granulomatous response, tuberculosis may well not be the only disease in which these assays can be applied with benefit.

PRIVILEGED SITE INFECTIONS

Both the APR and the granulomatous reaction require access to the site of infection for cells. A blood supply to the infected site is, therefore, essential for these reactions.

Very rarely, examples occur whereby organisms gain access to the body, typically as a result of bacteremia, and lodge in sites that either physically or functionally are beyond the normal immune system. The nidus of *S. aureus* infection encased within sclerotic bone that persists for years, even decades, known as Brodie's abscess has already been mentioned, but the best naturally occurring example is subacute bacterial endocarditis (SBE).

In SBE, classically the organism lodges on a previously damaged area of a heart valve. The organisms involved are typically of very low pathogenicity and would normally be extinguished rapidly by the APR/pyogenic response, but the almost avascular nature of the distal third of a heart valve cusp, exacerbated by fibrosis due to previous scarring, means that the site is 'privileged,' i.e. beyond the reach of the blood-delivered components of the pyogenic response, and, because cells of all kinds are denied access, even of the granulomatous response. Organisms multiply unhampered and a lesion comprising fibrin, platelets, and bacteria grows at the site – literally, a vegetation. Occasionally a fragment of the vegetation embolizes into the tissues, where the indolent organisms in the embolus are killed almost immediately. This paradox – a septic embolus resulting in a sterile infarct – illustrates well the unusual but typical nature of a privileged site infection. Accounts elsewhere in these volumes discuss the details of SBE. For the present purposes, it is important to note that the release of soluble antigens from the vegetation (bacterial cell-wall material, toxins, and other extracellular products) will stimulate humoral antibody production and this will typically go on over many weeks, if not months, before the true diagnosis is made by blood culture. This hyperglobulinemia is often unaccompanied by a significant APR (there is not the usual stimulus) and, for instance, the CRP is not very high (but it is raised) in SBE. Similarly, there may not be a leukocytosis of any note, although the dysglobulinemia usually

induces a so-called 'secondary' or sideropenic anemia. Prolonged IgG production may eventually result in damaged or abnormal IgG being circulated, and this may provoke an IgM response, leading to the classic setting for production of rheumatoid factor (RF). A positive RF is found in approximately 60 percent of patients with SBE.

Since much of the IgG produced in SBE is nonspecific and also because the antigenic analysis of streptococcal cell walls is little studied, the humoral antibody response in SBE is hardly ever used for etiological diagnosis. Fortunately, blood culture is a very reliable test under these circumstances and little is therefore lost. However, serology can occasionally be useful, typically when it is either difficult or dangerous to isolate the organism from the blood. The best illustration is the diagnosis of Q fever endocarditis, since this obligate intracellular Rickettsia-like organism is both difficult to grow and very highly infectious to laboratory workers. However, the serological diagnosis of Q fever has an additional merit that, once again, illustrates the practical utility of bacterial immunoserology.

It has been found that *Coxiella burneti*, the causative agent of Q fever, can exist in two quite distinct antigenic phases. Serial passage of the organism in guinea pigs, results in a preparation said to be in phase I, whereas culture in fertile hens' eggs yields an organism in phase II. In uncomplicated Q fever infection, which usually presents as an atypical pneumonia, only antibodies to phase II antigens can be detected by CFT. However, in either of the two recognized chronic complications of Q fever infection, endocarditis or granulomatous hepatitis, antibodies to phase I antigens also appear (Raoult et al. 2000). Thus, bacterial immunoserology, in this case, will confirm Q fever infection, say in a respiratory infection serology screen, but will also alert the investigator to the possibility of complications.

From the above account, it should now be clear that much bacterial immunoserology depends on the detection, characterization, and quantitation of humoral antibody. It is now necessary to discuss in outline how this is accomplished.

THE TECHNOLOGY OF ANTIBODY DETECTION

Whenever tests are said to 'detect antibody,' they are in fact techniques that allow us to visualize or to infer, often indirectly, that an antigen–antibody reaction has taken place. With a few exceptions (antibody-mediated lysis and serum bactericidal tests, for instance, neither of which are routinely used in bacterial immunoserology), the test-tube event does not replicate an in vivo event.

It is common practice for all serological tests to be conducted on an initial dilution, even if only for screening. This is because neat human serum contains low titers of a wide range of nonspecific antibodies of no diagnostic significance, and these are best disposed of by a simple initial dilution step. Thus, serological tests are often reported as 'titer <1/8,' rather than 'negative,' but the meaning is the same. There are, however, exceptions, the most common being the VDRL, which is reported as 'positive/negative in neat serum or at a specific titer.' However, it should be remembered that reagin is not an antibody in any case.

The following brief account gives a range of examples of techniques commonly used, but it does not give other than outline details.

Direct visualization of an antigen–antibody reaction

Agglutination is one of the oldest techniques and depends on the simple observation that whole bacterial cells will form aggregates in the presence of an antibody specific to a cell-surface antigen, the lattice formed by the action of the divalent antibody and the bacterial particles becoming a visible aggregate. Classically, antibodies to flagellar (H) antigens produce a delicate floccular appearance, those to somatic (O) antigens a granular appearance, and those to capsules a disk-like appearance within the fluid. The appearance of the supernatant fluid (after settling) is said to be 'water clear' in contrast to the milky and smooth appearance of the original bacterial suspension. The Widal test best exhibits these different agglutination phenomena. Agglutination can be demonstrated in test tubes (special tubes such as Dreyer's tubes were devised for this) but can also be shown on slides. However, for the latter, the antibody levels in the serum must be very high and the bacterial suspension must be very dense. It will still be necessary to do a tube test to assess the titer, but slide agglutination is often used as a rapid preliminary screening technique.

Variations on the agglutination theme include passive (heme)agglutination in which an antigenic extract of the organism is coated (by various chemically assisted processes) on to the surface of inert carrier particles, most commonly red cells, which will then (heme)agglutinate in the presence of the appropriate antibody. Tests can be made very precise indeed if a recombinant antigen is used. Other commonly used inert particles include latex and gelatin.

A new, very exciting, and highly sophisticated development of these relatively simple principles is the binding, severally, of a range of different antigens to the surfaces of a matched range of differently colored inert particles, the chromophores used being detectable by fluorescence. Antibody-induced or antibody-dependent changes in any one or more of the subpopulations of particles of a specific 'color' can be rapidly, accurately, and objectively detected using multiplex differential flow analysis (Opalka et al. 2003). In this way, antibody to one or more antigens within a panel of a much greater

number can be measured in one reaction. There are now several commercial systems available. The system can be reversed, so that the particles are coated with diverse antibodies, thus allowing the detection of more than one antigen in clinical material within a single screening test.

Lastly, the agglutination tests described thus far all detect divalent antibodies (IgG and IgM) in which the antibody links two (or more) particles to thus build up the lattice. Agglutination tests can also be used to detect monovalent antibody (IgA), which will ordinarily only coat the antigen-bearing particles, whether bacterial cells or carrier particles, but not cross-link them and, therefore, not result in visible agglutination. If, however, following washing of the IgA-coated suspension, antihuman (e.g. mouse, rabbit, goat, and so on) divalent IgG is added, a lattice will form. The resultant agglutination will indicate the presence of specific IgA.

Precipitation results when a soluble antigen meets the appropriate antibody. It can be demonstrated simply by allowing two liquids to meet at an interface whereupon a precipitate will form.

If both liquids are allowed passively to diffuse towards each other in a solid but transparent matrix, for instance clear agar or agarose gel, a visible precipitin line will form where they meet. This passive (immuno)diffusion, or double diffusion, has two additional properties. First, it will reveal the presence of more than one antigen–antibody system within the same reaction since they will form separate lines. Second, double diffusion will confirm the identity/nonidentity of any two systems if they meet. If they differ, the lines will not merge, but if they are identical, the lines will smoothly merge (the so-called 'reaction of identity'). This is because the precipitate will always redissolve in an excess of either reactant (antigen or antibody). These two reactions and the third possible outcome indicating partial identity are all well illustrated in the classical double diffusion method for the detection of diphtheria toxin production, the Elek plate, although it is a test for antigen and not antibody.

Precipitation methods can be speeded up considerably by applying an electric field across the gel, so driving the antigen and presumed antibody towards one another (immunoelectroosmophoresis (IEOP) or countercurrent immunoelectrophoresis (CIE)).

Indirect visualization of an antigen–antibody reaction

The general principle used here is that a secondary visible system, itself an antigen–antibody reaction, is used to infer that the sought for and invisible reaction has occurred.

CFT is the oldest and still the most widely used example. In this method the patient's serum and the antigen are mixed and allowed to react, but in the presence of complement. If the (invisible) reaction occurs, complement will be consumed ('fixed'). The fact that the complement has or has not been consumed can be demonstrated by the addition of a second system comprising animal red cells coated ('sensitized') with an antibody to the red cells raised in another (animal) species. If complement remains, the red cells will undergo complement-mediated immune lysis; if it has been consumed, no lysis will follow and, commonly, the red cells sediment to a button. No lysis therefore implies that the antibody sought has been detected and lysis implies that it is absent.

CFTs are inexpensive and popular because the reagents are relatively cheap and easily accessible. However, CFTs can be very difficult to standardize and there are many pitfalls in their use. Nonetheless, the CFT approach was the first semiautomated and generic antibody detection and screening system in microbiology.

Indirect immunofluorescent antibody tests (IFAT) utilize a similar principle to CFTs but confirm that immunoglobulin has been bound to the antigen by detecting it using an antihuman immunoglobulin tagged with fluorescein. The antigen is almost always solid, being cells from a culture or even a sample of tissue within which it is known that the whole organism can be seen. It is important to ensure that all unbound traces of serum are washed from the preparation prior to applying the detection system. Antihuman antibodies can be raised that are specifically of either the IgM or IgG class, thus enhancing the usefulness of the technique.

Obvious disadvantages of this method are the fading of the fluorescence after some time, making standardization and archiving very difficult. Quantitation of the antibody detected, even by titration to a poorly defined endpoint of fluorescence extinction, is subjective. The method, however, has the advantage of detecting exactly where in the tissues the antibody can be found.

EIAs take the indirect detection principle in a direction that solves many of the problems outlined above. Although there are many variations on the theme, the essence of EIAs is the production of a sandwich comprising (1) the antigen (whether a crude organism preparation, an extract of the organism or, increasingly, a recombinant antigen); (2) the patient's serum as a putative source of the antibody; and (3) an antihuman globulin tagged with an enzyme. As with IFATs, if the antigen–antibody reaction occurs, the enzyme-tagged antibody will become attached. The enzyme is then made to convert an appropriate substrate to a visible product. Enzymes commonly used include alkaline phosphatase and peroxidase. In both cases, the color intensity can be read on a colorimeter and the amount of antibody (a value equivalent to the 'titer') can be determined and compared with that of other samples.

EIAs have several distinct advantages and have become one of the workhorses of bacterial immunoserology. First, the 'antiantibody' nature of the detector system makes it possible to produce EIAs specific for IgM, IgG, or IgA antibody detection. Second, the stability, reproducibility, and standardizability of the end-product make EIAs excellent assays for automation, in turn making them quicker, cheaper, and less subjective.

However, EIAs remain individual reactions, capable of detecting only one antibody at a time. The multiplex differential flow analysis technology outlined above is, therefore, likely to be a strong competitor, able to detect several antigen–antibody reactions in one assay.

Other antibody assay techniques

Other, rarer, methods have been devised to detect antibody. Many are historical curiosities and can be dismissed, having been replaced by one or more of the above techniques. Nonetheless, they demonstrate the basis of bacterial immunoserology as a practical response to a clinical need and so will be briefly mentioned.

Toxin neutralization tests allow the detection of an antibody, in this case literally an antitoxin, by showing that the patient's serum will abolish the toxicity of the antigen. Thus, a cytopathic effect (CPE) of a toxin on a tissue culture monolayer will be prevented by the addition of immune patients' sera. Other examples include the inhibition of hemolysis due to a wide range of hemolytic extracellular toxins (such as streptolysin O, staphylococcal α-lysin), intradermal tests in animals, and even tests designed to show that immune serum will prevent a specific lethal or morbid reaction in an animal (such as the paralytic effects of tetanus or botulinum toxins, or the lethality of diphtheria toxin).

Thankfully, almost all of these animal assays have been successfully replaced by modern assays in which animals are not used, although equivalent sensitivity has not always or easily been achieved. In those bioassays that remain, it should be obvious that control reactions are absolutely vital, more so than in any other assays, because of the immense biological variation that there must inevitably be in the assay components.

Immobilization assays make use of the fact that many microbes have the property of locomotion (motility) and an immune serum will immobilize them. The TPI has been discussed above. Immobilization assays are prone to the particular problem that other inimical substances in the patient's serum, most commonly antibiotics, can produce an identical result to that of antibody.

Metabolic assays are a derivative of toxin and mobility assays since they capitalize on the fact that immune serum will either kill the organism or, as in this case, prevent it expressing a particular and easily measured characteristic. Thus, antibody to *Mycoplasma pneumoniae* can be detected by showing that the patient's serum will prevent the mycoplasma growing and metabolizing glucose, this property being manifest by a color change in the reaction tubes. Clearly, antibiotics will produce an identical effect.

COMMON APPLICATIONS OF ANTIBODY ASSAYS IN ORGANISM GROUPS

Staphylococci

In general, because of the pyogenic nature of staphylococcal infection, immunoserology is not needed. There are two exceptions. First, in suspected long-standing and deep-seated infection (see Brodie's abscess, above) in which samples for culture are difficult to obtain, recourse is made to the antistaphylolysin test, a hemolysin inhibition test, utilizing the α-hemolysin of *S. aureus* as antigen. When antibody is detected, the test is very predictive of chronic infection with *S. aureus*. Unfortunately, a significant minority of *S. aureus* strains do not produce the α-hemolysin, so negative results do not exclude infection. EIAs have also been devised testing for antibodies to the universal *S. aureus* antigen, ribitoltechoic acid (Ayyagari and Pal 1991), and seem promising.

Second, the propensity of coagulase-negative staphylococci to cause chronic infections of prosthetic material (a 'privileged site infection'), especially in replacement joints, but also in cerebrospinal fluid (CSF) shunts and indwelling intravascular devices, has led to the development of EIAs for antibodies to the glycocalyx ('slime') (Elliott et al. 2002) that such strains produce in abundance. These assays have the extra merit of confirming or denying the likely significance of isolates of these otherwise ubiquitous contaminants in tissue and blood cultures.

Streptococci

The need to relate recent *Streptococcus pyogenes* infection to postinfective sequelae, such as rheumatic fever, acute type 1 nephritis, and rarer events such as erythema nodosum and Henoch–Schoenlein purpura, has provoked the development of a range of assays, all originally based on the principle of neutralizing the effect of an extracellular product of *S. pyogenes*.

The most common by far is the antistreptolysin O titer (ASOT). Since, however, *S. pyogenes* infections of the throat and middle ear are common and the number of different (M protein) types is so large, some background level of ASOT is almost inevitable in any population. Thus, a 'positive' ASOT is usually defined as a value in excess of the norm for the population from which the individual to be tested comes. Alternative

tests such as antiDNAse B and antihyaluronidase are more rarely performed but remain necessary since *S. pyogenes* infections of skin (streptococcal pyoderma), which can be followed by nephritis but not rheumatic fever, rarely give rise to a raised ASOT, whereas the other antibodies will rise (Ferrieri et al. 1970). *S. pyogenes* throat infections, however, reliably provoke ASOT rises. Unrelated infections and, rarely, infections due to streptococci of other Lancefield groups can also occasionally provoke a raised ASOT, giving another useful role for the second line tests. Nowadays, especially with the availability of recombinant antigen technology, these antibodies are more commonly detected by passive particle agglutination tests or EIAs rather than the classical neutralization approach.

Much recent interest has been targeted on devising a reliable antibody test for infection due to *S. pneumoniae* (the pneumococcus). New vaccines offer the prospect of broad and enduring protection but will need accurate evaluation. The diversity (>90 types) of the capsular polysaccharide antigens makes simple tests unlikely, although the multiplex differential flow analysis technology may greatly help, and attention has centered on the universal pneumococcal product, pneumolysin, which is of the same family of thiol-activated toxins as Streptolysin O. Progress has been hampered until recently because it is found only intracellularly and cannot, therefore, be produced in large amounts. However, recombinant protein technology has solved this problem and assays are being developed (Lankinen et al. 1999). Other targets are also under study.

Corynebacteria

The principal immunoserological need is for the detection of diphtheria antitoxin prior to, and subsequent to, immunization. Although EIAs have been developed, experience suggests that (in contrast to the detection of the toxin itself; see below) they are insufficiently sensitive. The standard assay presently consists of a toxin neutralization assay using the CPE in Vero cells. This assay has replaced the subjective and complex skin test previously used, the Schick test.

Clostridia

The highly virulent exotoxins of *C. tetani* and *C. botulinum* produce the characteristic diseases with which they are associated at concentrations below those necessary to immunize – a conundrum that should lead all doctors to remember that their last duty to a patient recovering from clinical tetanus is to immunize them with tetanus toxoid prior to discharge. Therefore, antitoxin assays are not used in diagnosis. However, assays to detect high titers of *C. tetani* antibodies following repeated immunization with toxoid have been devised to select donors for the production of human tetanus immunoglobulin for treatment purposes.

Neisseria

Antibodies to *Neisseria meningitidis* are not commonly assayed for diagnostic purposes, although they have occasionally helped in retrospective diagnosis of the serogroup involved in an outbreak. The most common circumstance requiring a noncultural approach, the failure to culture *N. meningitidis* from blood or CSF, is now addressed through polymerase chain reaction (PCR) of these specimens. PCR is quicker, more revealing, and more sensitive than immunoserology.

However, antibody tests for *N. meningitidis* have been invaluable in assessing the efficacy of vaccines, particularly those for *N. meningitidis* serogroup C. Although many different assays for antibodies to many different antigens have been devised, the classical bactericidal antibody test remains the specified method for vaccine licensing purposes.

There are no currently useful assays for antibodies to *N. gonorrhoeae*. The gonococcal complement fixation test (GCFT) continues to be requested and even promoted in some textbooks. However, many investigations have shown that it is very rarely helpful and often is misleading in an area of diagnosis that has considerable medicolegal potential.

Enterobacteria (here taken to encompass most nonfastidious aerobic gram-negative bacilli)

The Widal reaction for enteric fevers (typhoid and paratyphoid) has already been discussed (see above). It should be emphasized that these methods cannot and should not be applied to nonenteric fever *Salmonella* species. The sharing of antigens (especially O antigens) between species makes the results impossible to interpret. No useful routine antibody assays are in current use for infections with shigellae.

The recent recognition of serious infection with *Escherichia coli* O157 has stimulated the development of an EIA to detect antibody to the lipopolysaccharide antigen of its cell wall, incorporating the O antigen. Judicious use of this Reference Laboratory test has given invaluable help in identifying unrecognized cases prior to an outbreak and in rapidly determining the true extent of an outbreak by testing apparently unaffected subjects (Chart 1999).

Although numerous antibody tests have been developed from time to time for various research studies, there are few other established assays used for diagnosis of infections with the remaining organisms within this group. However, an assay for antibodies to *Campylobacter jejuni* is frequently requested for a tangential

purpose. It has emerged that the most common preceding event to the onset of Guillian–Barre syndrome is *C. jejuni* infection. The relationship is thought to be based upon cross-specificity of *C. jejuni* antigens and certain epitopes in neural tissue, a situation dubbed molecular mimicry (Schwerer 2002).

Parvobacteria (fastidious gram-negative cocco-bacilli)

Serology is still used for the diagnosis (using paired sera) of infection with *Bordetella pertussis*, but as with *N. meningitidis* (see above), the most common reason for the test is for confirmation of clinically suspicious but culture-negative cases, especially in adults, older children, and 'partially vaccinated' children. As with *N. meningitidis*, this need is increasingly being met by PCR-based testing. The demand for serology, which is complex and the results of which are difficult to interpret, is likely to diminish.

Apart from research settings and studies for the evaluation of vaccines, serology is little used in the diagnosis of infections with *Haemophilus* spp. The immunoserology of *Brucella* was discussed earlier. There is an occasional rare need for antibody assays in melioidosis, and a passive hemagglutination test using *Yersinia pestis* Fraction 1 antigen is used in the serodiagnosis of plague. In both diseases, isolation of the causative organism is much the most common diagnostic method.

In tularemia, however, diagnosis is commonly made by demonstration of a rising antibody titer, since the clinical appearances are often confusing. Cross-reactions with *Proteus* spp. (see below) and *Brucella* spp. antigens can occur. Such is the complexity and diversity of *Francisella tularensis* strains and their antigens that interpretation is an expert matter. Nonetheless, serodiagnosis is an attractive option given the highly infectious nature of *F. tularensis* and the danger of laboratory-acquired disease.

Legionella

Antibodies to *Legionella pneumophila* were originally detected by IFAT using a formalized yolk-sac culture of the organism on a slide as the antigen. High and, preferably, rising titers are diagnostic. It was noted from the start that antibody might take up to 3 weeks to appear after the onset of the illness.

EIAs have now largely replaced the IFAT, and PCR of tracheal secretions or bronchoalveolar lavage fluid and urine antigen assays have supplemented serology. However, all these tests are specific for *L. pneumophila* infections, which account for nearly all cases of legionnaires' disease. Investigating infections with one or more of the nearly 40 'other legionella species' (sometimes called fluorobacters) in highly immunosuppressed patients is a task for an expert.

Low and unchanging levels of antibodies to *L. pneumophila* can be found in Pontiac fever, an extrinsic alveolitis (but not a pneumonia) triggered by inhalation of *L. pneumophila* antigens from colonized or contaminated air conditioning systems and, as such, one of many forms of 'sick building syndrome' (Friedman et al. 1987).

Mycoplasma pneumoniae

Interest in the serology of this common organism is three-fold. The technology is rather mundane, most cases being diagnosed by a rising antibody titer using a CFT or by detection of specific IgM using an EIA.

The first point of note is the association between serological evidence of infection with *M. pneumoniae* and various neurological conditions, most notably Guillian–Barre. As with the previously mentioned association with *C. jejuni* infection, there is good evidence that cross-reacting antibodies are the basis of this problem (molecular mimicry) (Kusunoki and Kanazawa 2001). Second, there is a similar association with acute pancreatitis.

The third point of interest harks back to the early empirical days of bacterial immunoserology. It was noticed many years ago that patients with 'atypical pneumonia,' a condition not then known to be due to *M. pneumoniae*, often exhibited cold agglutinin antibodies (CAA) in the early stage of the disease, the titer of which appeared to correlate with the severity of the illness. In fact, the CAAs are IgM class antibodies produced in the acute stage of the infection. Their specificity and evocation are still uncertain. They do not, for instance, react with the antigen used in the CFT. They are, however, relatively specific, being found only in pneumonias and nearly always only in those due to *M. pneumoniae*. Their very early appearance in the illness can be capitalized upon in a very simple bedside test (Davidsohn and Wells 1962).

Freshly drawn blood is mixed four parts to one with citrate in a small glass tube, the anticoagulated blood sample then being placed in a refrigerator or on ice for a few minutes. If CAAs are present, large aggregates will form and can be seen if the blood is run over the glass surface. These readily disappear on hand-warming of the tube and can be redeveloped by its return to the cold. Samples with this result can be taken to contain CAA titers of at least one in 80 and a presumptive diagnosis can be made. Other causes of cold agglutinins must also, obviously, be considered in certain settings.

Rickettsia

Diagnosis of rickettsial disease is usually by IFAT, but this may not distinguish between the different forms of

typhus (epidemic louse-borne, murine, scrub, etc.). Washed and adsorbed antigens can be used to achieve these distinctions, which are of both diagnostic and epidemiological importance. However, recourse can still be made to yet another empirical bacterial immunoserology test, the Weil–Felix reaction. This relies on the observation that the serum of patients with these differing rickettsial infections will agglutinate different suspensions of correspondingly different strains of *Proteus vulgaris*. Thus, sera from patients with epidemic louse-borne typhus agglutinate *Proteus* OX-19 strains, whereas sera from patients with scrub or mite-borne typhus agglutinate *Proteus* OXK strains. These easily maintained antigens were invaluable before rickettsial culture was possible and still retain their usefulness on occasion today.

The usefulness of bacterial immunoserology in the diagnosis and management of Q fever infection has already been discussed above.

Spirochetes

Serology is a common method for the diagnosis of leptospiral infection, since the best opportunity to see leptospira in clinical material, such as urine, is usually gone by the time the diagnosis is considered and microscopy (and culture, if attempted) is notoriously difficult.

At a group identity level, CFT can be used but it is increasingly overtaken by EIA, which can offer IgM-specific testing. However, microscopic agglutination tests with specific leptospiral antigens are necessary to identify the particular species involved, for instance *L. canicola*, *L. interrogans*, *L. icterohaemorrhagicae*, and so on. Borrelioses such as relapsing fever (*B. recurrentis*) are not usually diagnosed by serology.

The complex serological approach to syphilis (*T. pallidum*) has already been discussed in some detail. It should be added here that the same tests are used to investigate suspected infection with *T. pertenue* and *T. carateum*, the agents of, respectively, yaws and pinta, although serology cannot discriminate between them.

In recent years, Lyme disease has been added to the list of major spirichetal diseases. Lyme disease can be diagnosed by serology using EIAs with *Borrelia burgdoferi* antigens. Like syphilis, Lyme disease evolves through recognizable acute, latent, and chronic stages. Whilst humoral antibody assays are invaluable in diagnosis and following the disease, they may be unpredictable in both the time and magnitude of their appearance. EIAs are particularly troublesome in chronic Lyme disease and/or treated cases. There is a need to develop an equivalent to the VDRL to act as an index of activity. The advent of the evoked gamma interferon assays measuring cell-mediated immunity may be helpful in this.

Chlamydiae

Until recently, it was held that only two groups of *Chlamydiae* existed. These were group A (now known as *Chlamydia trachomatis*) and group B (*C. psittaci*). Since *C. trachomatis* largely caused infections of mucosal surfaces (trachoma in the eye, inclusion conjunctivitis, and nongonococcal urethritis), the need for serology was limited. Occasional invasive infection was recognized in the forms of salpingitis and infant pneumonitis and a specific subgroup of *C. trachomatis* was held responsible for the granulomatous genital infection known as lymphogranuloma venereum (LGV).

C. psittaci was accepted as an uncommon but well-recognized cause of atypical pneumonia (psittacosis or ornithosis), and almost all such cases were diagnosed serologically. It was convenient, therefore, to use a common CFT antigen, a mixture of an LGV strain and a *C. psittaci* strain, to detect all antibodies, the likely specificity being decided by the markedly different clinical circumstances. The recent discovery of a third species, *C. pneumoniae*, which causes pneumonia, appears to be of purely human origin, and antibodies to which may not always react with the old antigen (Blasi et al. 1998), has spurred the development of species-specific antibody tests, which are usually of a microIFAT basis.

Other comments

SALIVA TESTING

It is important to note that along with all the many advances in assay technology, there has also been an advance in specimen technology. This account thus far has assumed that all tests are carried out on serum (excluding those concerned with cytokine evocation from cells). Recently, there has been extensive investment in detecting antibodies of all immunoglobulin classes in ‘saliva’ or, more precisely, crevicular fluid (Akingbade et al. 2003). Special oral devices allow adequate volumes of sample to be obtained. Salivary testing is convenient, noninvasive, and particularly suitable for children and others with aversions to venepuncture. It is being taken up with increasing frequency.

NEAR-PATIENT TESTING

Unsurprisingly, the development of sophisticated systems for the direct or indirect visualization of antigen–antibody reactions, the ever-increasing precision and robustness of these technologies, and the benefits of modern mass-production techniques have all combined to promote near-patient testing kits. In addition to simply refining the methods outlined above, commercial houses have introduced some truly innovative approaches. For instance, it is possible to tag

detection monoclonal antibodies with gold particles, so that when the antibody localizes (having reacted with an immobilized antigen), its presence becomes macroscopically visible. All the necessary reagents can be offered in a cartridge format, including control reagents, and the addition of the sample under tightly specified circumstances can give a result within minutes, with no laboratory involvement.

Even more sophisticated approaches include embedding antigens or antibodies within membranes, the optical properties of which will alter if a reaction occurs, thus giving a visual signal of the event.

The potential variations on this theme are myriad and need not be listed here. However, whatever the technology employed, it is important to address three areas of concern:

1. Safety. Many of the near-patient kits require venepuncture, needle-stick, or other means of drawing blood. Since the instant diagnosis of diseases such as hepatitis B or HIV in the field is one of the attractive settings for such kits, it is important to attend to waste disposal of the kits (often catered for by the manufacturer) and the attendant materials (not always catered for).
2. Controls. Although all reputable kits come with control reagents and the results obtained will be reproducible if the instructions are carefully followed, all serologists and laboratory diagnosticians will be aware that these alone are an inadequate control framework. Diagnostic tests need to be continually challenged with archived and current 'wild' samples, thus allowing for possible events such as the effects of target mutation, epitope loss, and so on. These checks are part of laboratory systems but are unlikely to be available to individual clinicians. Arranging for patients to be cohorted or even to attend a clinic for testing destroys the essence of near-patient testing.
3. Inappropriate use in inappropriate contexts. The devolution of bacterial immunoserology testing to the bedside implies that a test will be performed by interested and well-motivated nonlaboratory personnel, the experience of whom will likely be confined to one medical specialty. Occasionally, therefore, a near-patient test system may be used outside the testing scenario for which it was designed. Under these conditions, very misleading results can occur, the consequences of which can be both unfortunate and embarrassing.

With careful planning and forethought and, most importantly, the ready cooperation of the conventional laboratory, all these problems can be resolved. Done well, near-patient testing will be an increasing boon to clinical care (Borriello 1999).

Lastly, it must also be remembered that the need to avoid sending specimens some distance to a laboratory can also be avoided by careful clinical assessment and the development of algorithms, which eventually may result in no specimens being required at all. An excellent example is seen in the long story of the attempts to optimize treatment of the 'strep throat' (Needham et al. 1998; Bisno et al. 2002; McGinn et al. 2003).

METHODS FOR THE DETECTION OF ORGANISMS AND THEIR PRODUCTS AND FOR THE CHARACTERIZATION OF ORGANISMS BY IMMUNOSEROLOGICAL MEANS

In this aspect of bacterial immunoserology, the principles, and largely, the technologies remain as before, but the purpose of the assays is to detect the antigen using the antibody as the tool. First, it is important to recognize the settings within which this noncultural approach is useful and then to understand the limitations and the alternative, nonimmunoserological means by which it can also be attempted.

Noncultural methods of diagnosis

Broadly, noncultural methods are used because of their speed or specificity or because they give useful information in circumstances in which culture is not possible. In this latter instance, this might be because the organism has never been successfully cultured or, more commonly, because prior antibiotic therapy has rendered culture useless.

Until recently, the major approach for noncultural diagnosis was by detecting a component of the organism by immunological means. Since antibodies were the essential reagent, it followed that the target had to be an antigen and this almost invariably dictated the choice of a surface component such as a capsule, flagellum, somatic antigen, and so on, or a secreted antigen, such as an exotoxin. Medical microbiologists continue to use a very large number of such assays. The technology used to detect the antigen–antibody reaction comprises the whole range described above (agglutination, precipitation, EIA, etc.), but there are some notable additional aspects.

Advances in antibody production and application

MONOCLONAL ANTIBODIES

In many cases a test used will have begun as a method using a polyclonal antibody raised in animals. The polyclonal antibody is now almost always replaced by a monoclonal antibody. This change has several important advantages but one important limitation. The advantages include the 'immortalization' of the antibody, or at least the hybridoma, the standardization of the antibody, thus removing batch variation problems at one stroke,

and the potential to generate antibodies of such potency that the sensitivity of the test can be exquisite and well beyond that of its polyclonal antibody-based predecessor.

However, since the monoclonal antibody is, by definition, directed towards only one epitope of the target antigen, the whole assay can be vitiated if this epitope is not universally present or, if, as occasionally happens, the organism mutates and loses it (Smith et al. 1996). The considerable and well-deserved reputation for the accuracy of monoclonal antibody assays can then be a hindrance to good practice. It is, therefore, often recommended that very important results, for instance identifications for medicolegal purposes or in the diagnosis of life-threatening conditions, be confirmed by alternative pathway tests or by a second monoclonal assay directed towards a different epitope.

COAGGLUTINATION

Protein A on the surface of well-characterized strains of *S. aureus* binds to the Fc component of IgG molecules, making it possible to coat suspensions of the inactivated organism with monoclonal antibody. The resultant preparation becomes a particulate suspension in which each particle exhibits on its surface the free Fab component of the IgG used. Thus, in the presence of the appropriate antigen (in whatever physical form), the staphylococcal suspension will agglutinate, a lattice having been formed by the antigen and Fab receptors, which also brings down the suspension. This assay format, known as coagglutination, is widely used. Suspensions can be stained in different colors for different Fab specificities and then mixed so that several antigens can be tested for at one time. In some assays, protein A is itself coated on to inert or passive particles (for instance latex or gelatin).

PHAGE ANTIBODY DISPLAY (PINI AND BRACCI 2000)

Phage antibody display (PAD) works on a simple principle, which is that it is possible to insert recombinant DNA sequences coding for antigen-binding fragments (Fab) of IgG into bacteriophages, which will then express the appropriate Fabs on their protein coats. In this way, a 'library' of such modified phages can be produced, which will contain an almost limitless variety of Fab specificities. Selecting one individual phage and cultivating it in a bacterial host becomes akin to growing a monoclonal antibody, but without the rest of the immunoglobulin in the final product.

The Fab-bearing phage can then be tagged with fluorescein to give the equivalent of a fluorescein-tagged monoclonal antibody for microscopy assays. Alternatively, immobilization of the phage on a surface, such as in the wells of an assay plate, can form the basis of an EIA. The details of the process whereby the appropriate phage is selected from within the original library are complex but are analogous to the old serological method of making a polyclonal antiserum more specific by serial adsorption of antibodies to closely related but ultimately undesirable antigens (technically described as 'panning'). This offers the prospect of producing equivalent reagents to monoclonal antibodies without the use of animals and more quickly.

However, PAD offers one further, potentially revolutionary advantage. The epitopes and 'antigens' to which PAD 'antibodies' can be 'raised' need not be constrained by their acceptability, or not, to any human or animal immune system. Thus, antigenicity and immunogenicity are irrelevant. As importantly, self- or autoantigens are not excluded as is the case in conventional raising of antibodies. The only real prerequisite is that the chemical group can be recognized by a Fab grouping on one of the phages.

Consequently, as yet unrealized differences in surface structures between two populations of bacterial cells can be explored as the basis of their reliable distinction, and reagents can be produced to do this reliably, quickly, and relatively cheaply. In the future, we may refer to nonimmunoserology tests.

APTAMERS (JAYASENA 1999; OSBORNE ET AL. 1997)

Aptamers are nucleic acid molecules that bind to specific ligands. Consequently, they can be used to link oligonucleotides to specific sites. If a pair of aptamers is targeted on to a protein (for instance, an epitope or an antigen), the PCR can be used to amplify a stretch of DNA or RNA corresponding to the nucleotide sequence that bridges the 'gap' between the aptamer-linked oligonucleotides. By this means, assays detecting zeptomolar (10^{-21} mol) amounts of the target can be devised.

Since the aptamers themselves can be synthesized, this system can rival antibody-based assays, yet, as with PAD, animals are not necessary and diversity is not necessarily confined by antigenicity or immunogenicity of the target.

COMPETITION WITH MOLECULAR ASSAYS

The major new change in recent years has been the influence of molecular biology, especially PCR. The ability to detect small amounts of DNA and the development of assays in which the PCR detects specific sequences indicative of certain organisms or their characteristic products has challenged the previous primacy of the antigen-detection immunoassays. PCR assays are, of course, also very quick, sensitive, and helpful if the organism cannot be cultured, is dead, or its growth is inhibited by antibiotics. However, it should be remembered that PCR assays also have problems. The reaction is very vulnerable to the presence within clinical material of substances inimical to the Taq polymerase enzyme ('inhibitors'). These are relatively common

(heparin, IgG, and so on), whereas immunoassays do not suffer these problems.

Furthermore, the genomic assay can detect the gene that confers on the organism the ability to produce a given product, e.g. a toxin, but the gene may not be expressed. In diseases such as diphtheria, which is defined almost totally by the actions of the toxin, mere detection of the gene is insufficient to make the diagnosis. It is the phenotype that infects and/or causes disease.

It seems likely that the immunoassays will be needed for some time to come and that the two approaches should be complementary rather than competitive.

COMMON APPLICATIONS OF IMMUNODETECTION ASSAYS IN ORGANISM GROUPS

Staphylococci

The never-ending search for a test with the simplicity and speed of the slide coagulase reaction and the accuracy of definition of the tube coagulase reaction in this most ubiquitous of human pathogens has led to the development of a whole range of assays. Almost all of the recognized formats have been deployed. Since speed was an important objective, reverse passive hemagglutination, passive particle agglutination, and coagglutination, have been especially popular. These assays have variously targeted coagulase itself (here being detected as an antigen and not an enzyme), capsular antigens, and fibronectin receptors, amongst others. Almost all such tests are very nearly as accurate as the definitive tube coagulase test (Summers et al. 1998).

A widely used innovation has been the identification of methicillin resistance in *S. aureus* by EIA or passive particle agglutination immunodetection of penicillin binding protein (PBP) 2A on its surface by monoclonal antibodies, thus identifying methicillin-resistant *S. aureus* (MRSA) in a few minutes (Naratomi and Sugiyama 1998).

Streptococci

One of the classical applications of the precipitin reaction was the Lancefield grouping of β-hemolytic streptococci in which the extracted 'C substance' (a carbohydrate) was identified by layering a series of group-specific antisera on to aliquots of the extract in capillary tubes and observing a precipitation reaction at the appropriate interface. Nowadays, expectedly, this has been replaced by a passive particle assay, usually by slide agglutination, using particles coated with a series of group-specific monoclonal antibodies.

S. pneumoniae is commonly identified by a series of rapid tests, one of which is a slide agglutination test targeting a C substance common to all pneumococci.

Pneumococci also provide a good example of an unusual form of the precipitin reaction. They can be typed by the capsule swelling or Quellung reaction. This is based on the observation that if pneumococci in broth culture are microscopically observed before and after the addition of the homologous capsular antiserum, the capsule appears to swell dramatically in size. In fact, the capsule is at least 90 percent water and continually dissolving into the surrounding medium. It is a soluble antigen that precipitates when in contact with the appropriate antibody. This increases its refractivity and thus it appears to swell in the presence of the antiserum.

Pneumococcal infections illustrate another use of immunodetection. During invasive pneumococcal disease, it is often possible directly to detect capsular antigen in CSF, blood and urine, by passive particle agglutination (usually latex) or by EIA. The diversity of the capsular antigens (>90 serotypes) and their polysaccharide nature mitigate against a monoclonal antibody approach so that antigen detection is not as sensitive as culture. It has the merit of being suitable when culture is likely to be unrewarding. Students of the potential pitfalls of immunoserology will realize that antigen will be detected in the urine of the recently vaccinated.

Corynebacteria

Mention has already been made of the Elek double diffusion plate method for the detection of diphtheria toxin production in isolates of *Corynebacterium diphtheriae* or, more rarely, in some strains of *C. ulcerans*.

More recently, toxin production has been assayed by EIA. In either instance, it is important to understand that these tests demonstrate toxin synthesis, whilst the PCR often used to screen strains merely demonstrates the presence of the gene (see above).

Clostridia

The many exotoxins of clostridia are highly antigenic and are a potentially rich field for immunoserology. However, many of those of human interest, classically tetanus toxin and botulinum toxins, are still assayed when required by animal tests, although EIAs are being increasingly applied. These are Reference Laboratory tests. However, routine bacterial immunoserology includes two clostridial assays.

The first is the Nagler reaction. In this unusual format, the production of a lecithinase by an organism thought to be *Clostridium perfringens* is demonstrated by streaking the organism on to an egg-yolk medium. The further demonstration that the lecithinase produced is

the α toxin of *C. perfringens* (there are other lecithinases) is shown by the specific neutralization of the effect of the enzyme on the egg yolk on one half of the medium that was pretreated with specific antitoxin. The organism will grow on both halves of the plate. The Nagler reaction thus permits a secure identification of *C. perfringens* overnight. It should be noted that mere demonstration of lecithinase activity without neutralization is not the Nagler reaction.

Second, detection of the toxin(s) in the liquid stool of an affected patient is an essential prerequisite for the diagnosis of *Clostridium difficile*-associated disease (CDAD). Originally, this was accomplished by detecting a CPE in cell cultures (several were used, the most common being Vero cells) and then confirming that the CPE was neutralized by appropriate antitoxin. Although *C. difficile* antitoxin can be produced, it is common practice to use *C. sordellii* antitoxin, which was first used. There is a very high degree of homology between the two toxins. It is also important to note, contrary to widespread belief, that the neutralized cytotoxin assay so produced detects both *C. difficile* toxins, A and B.

Although the neutralized cytotoxin assay remains the gold standard, its possible subjectivity and relatively long turnround time have stimulated the search for more standardized and quicker tests. These are usually in EIA format. An adequate replacement assay for the cytotoxin test must detect both toxins A and B by an immunological pathway.

Neisseria

There are several monoclonal antibody-based tests using a variety of formats, which can confirm the identity of a suspect isolate as *N. gonorrhoeae*. Over-reliance on any one such assay, the accuracy of which is, after all, vulnerable to a change in only one epitope, can be problematic in practice. Gonococcal identity should, therefore, be investigated in parallel by an alternative pathway test, for instance sugar fermentation tests. A second monoclonal test (directed to a different epitope) might also be necessary on occasion.

Rapid serogrouping of isolates of *N. meningitidis* is very important since it influences case management, especially the decision to vaccinate close contacts. It is usually performed with assays similar to those used in streptococcal grouping or the identification of pneumococci (see above).

Enterobacteria

The use of antibodies to analyze the antigenic make-up of Enterobacteria is very widely used. A classic application is the identification of salmonellas by analysis of their O and H antigens (the Kaufmann–White scheme). Shigellas can be identified in an analogous way, although since these nonmotile organisms do not display H antigens, it is necessary to use adsorbed O antisera and some supplementary biochemical tests.

Within the species *Escherichia coli*, there are several identification schemes based on serological analysis. Thus, the identification of enteropathogenic *E. coli* is based on O antigen analysis. Serological analysis plays a part in identifying enteroinvasive and other pathogenic strains.

It is in identifying *E. coli* O157 isolates, however, that serology is most commonly used. Colonies of putative *E. coli* O157 growing on a selective medium can be screened for further investigation by slide agglutination with an O157 antiserum. However, before being accepted as the cause of disease, the organism must next formally be confirmed to be *E. coli* and, secondly, to be elaborating one or both of the verocytoxins (VT1 and/or VT2). Final proof is obtained by toxin gene PCRs and an EIA for VT1 and VT2. This process re-emphasizes the important principle that O antigens are shared within and even between species of Enterobacteria. Serological analysis must, therefore, always be assessed within a context.

Parvobacteria

Serology can be used to identify and type *Brucella*, *Yersinia*, *Francisella*, and other Parvobacteria, but in common practice it is *Haemophilus influenzae* that attracts the most attention. *H. influenzae* is divisible into six capsular serotypes, A–F, often called Pittman types. These can be identified in capsule swelling (Quellung) reactions using specific antisera. *H. influenzae* capsule type B, often abbreviated to HiB, is responsible for the overwhelming majority of severe human infection, which is predominantly in childhood. HiB meningitis, septicemia, pneumonia, osteomyelitis, and epiglottitis are all life-threatening diseases. Recently, HiB vaccination has successfully controlled these diseases, but it is necessary to maintain vigilance. All isolates of *H. influenzae* from frankly pathogenic circumstances merit examination for the B antigen. Serotyping can now be performed in simpler formats than capsule swelling.

It should be noted that 'noncapsulate' *H. influenzae* is very commonly isolated from the sputum of adult patients with exacerbations of chronic bronchitis and bronchiectasis, but this is not the setting for HiB.

Meningitis screening

It is common practice to examine samples of CSF, especially those samples with a pleocytosis or other markers of bacterial meningitis, for capsular antigens of *N. meningitidis*, *S. pneumoniae*, and HiB. Whilst these tests are occasionally valuable and the effort is laudable, it should be remembered that these tests are designed

primarily to identify organisms, i.e. under circumstances in which antigen is in plentiful supply.

In contrast, in CSF for instance, it has been estimated that up to 10^6 organisms/ml may be needed to detect antigens reliably (West and Nasrallah 1988). Therefore, negative results do not exclude the disease. It is in such circumstances that the new approach of PCR is often preferable, being more sensitive and, when necessary, also capable of pointing to other properties of the causative organism, such as antibiotic sensitivity or resistance (Kearns et al. 2002).

Legionella

The slow growth of these organisms in culture and the unusually slow appearance of detectable antibody in the patient's blood have been stimuli to develop alternative diagnostic means. The detection by EIA of a cryptic antigen of *L. pneumophila* in the urine of infected patients has proven to be a very successful approach. These tests (several are available) have greatly enhanced patient management in individual cases. Their simplicity and rapidity have also assisted outbreak investigation.

Two caveats must be applied. First, the tests are effectively restricted to diagnosing infections with *L. pneumophila*. These tests cannot, therefore, assist in the diagnosis of infections, usually of highly immunosuppressed patients, with other *Legionella* species, such as *L. bozemanii* (Humphreys et al. 1992). Second, the antigen may continue to be excreted for extraordinarily long periods after first becoming detected, even if the clinical course has been benign and response to treatment has been good.

Monoclonal antibodies are used in Reference Laboratories as an important tool in identifying and typing legionella species.

CONCLUDING REMARKS

The above account is not exhaustive, but it gives some idea of the extent, diversity, and utility of current bacterial immunoserology practice. Although, inevitably, future technical advances will continue to be incorporated into this area of diagnostic microbiology, the principles remain the same. It is likely that bacterial immunoserology will continue to be an important element in medical practice.

Classification systems to clarify risk	3	References	9
Prevention of infections	5		

INTRODUCTION

Laboratory biosafety is the active, assertive process based on evidence-based principles to ensure safety from microbial contamination or infection, or toxic reaction for workers, the public, and the environment as a result of the active manipulations of live microorganisms or their products while pursuing academic, research, industrial, and clinical investigations. The goals are to prevent laboratory-acquired infections in workers and to prevent accidental releases of live agents that can potentially endanger and have severe negative impact on humans, animals, and plants. Laboratory safety involves all aspects of the laboratory cycle, starting from before microorganisms arrive in the facility, through to the training of personnel, and the establishment and monitoring of safe working practices, through the proper use of reagents, materials, and equipment, through the safe storage and transport of agents, and ultimately to the terminal sterilization and destruction of microorganisms.

EPIDEMIOLOGY OF LABORATORY-ACQUIRED INFECTIONS

Laboratory-acquired infections are generally defined as infections that likely occur while handling offending organisms during the analytic phase of laboratory testing. Usually, this is an epidemiological conclusion, based on the presumption of low likelihood of a concurrent community exposure, although with molecular or other identifying techniques the likelihood of another source can be reduced or eliminated. It is important to appreciate that the testing cycle begins well before the sample actually reaches the laboratory (the preanalytic phase of laboratory testing). In one of the original studies of laboratory-acquired infections, infections acquired during the collection of some samples were included if it could be ascertained that the collection was solely for the purpose of a laboratory investigation. Infections experienced by phlebotomists as a result of needlestick injuries are now routinely included as laboratory acquired infections. Arbitrarily, phlebotomist infections with chicken pox acquired while collecting samples in patients rooms are often not included (Collins and Kennedy 1999).

Although difficult to date precisely, the first microbiology laboratories were active by 1840–60, with the laboratories run by pioneers including Pasteur and Koch. The first report of a laboratory-acquired infection was in 1899, with the reporting of Mediterranean fever.

The study of laboratory-acquired infections was not carried out in a systematic fashion until 1951 with the most extensive and historic survey of 5 000 American laboratories by Sulkin and Pike (Collins 1983). This work was extended by three additional series (Sulkin

1964; Pike et al. 1965; Pike 1976). Through these reports, the authors cited 3 921 laboratory infections dating between 1930 and 1974, with a mortality of 164 (4.1 percent).

Of note, 2 307 (58.8 percent) of the infections were reported from research facilities, 677 (17.3 percent) were from diagnostic facilities, 134 (3.4 percent) were from the generation of biological products (industry), and 106 (2.7) were from teaching facilities. The remaining 697 (17.8 percent) were unspecified by source.

From four series performed in the UK between 1971 and 1991, it was noted that within clinical facilities, the majority of infections were reported from workers in the microbiology laboratory, with the second most common department being morbid anatomy. Of note, over the 20-year period, using the format of single-year surveys, the number of infections reported dropped over 80 percent, from 104 to only 17.

All studies are hampered, however, by having access only to those laboratory-acquired infections that are officially reported, either in literature or through other database systems. In no jurisdiction is there open access to required laboratory-acquired infections reporting. It is assumed that even complete listings reflect an immeasurable minority of infections that indeed occur (Sewell 1995).

Microorganisms are transmitted by a limited number of routes, which includes generation of aerosols of respirable size affecting the lungs or nonrespirable size resulting in contamination of external surfaces. Contamination of surfaces also result from spills, leaks, and untidy work practices. Ingestion results from contamination of edible or nonedible oral substances that reach the mouth as a consequence of contaminated hands, contaminated foods, or unsafe practices such as mouth pipetting. Laboratory accidents, especially involving the use and abuse of sharp instruments or breakable glass, result in puncture wounds of potentially fatal outcome. Inadvertent exposures resulting from inadequately identified or improperly stored reagents and materials, can result in serious, preventable infection. A laboratory risk assessment recognizes the potential routes and limits their ability to function.

While laboratory factors including aerosols, splashes, and accidents are described as major causes of laboratory-acquired infection, so too are human factors. In four series between 1952 and 1976 (Pike and Sulkin 1952; Reid 1957; Pike 1976; Harrington and Shannon 1976), it was repeatedly demonstrated that most workers who developed infection had had prior laboratory training. While at first blush this would appear to be problematic, it is also this group that would be performing the vast majority of hands-on activity. Disturbingly, it has also been pointed out that three of four surveys have indicated that 7–8 percent of laboratory infections occur in clerical and maintenance personnel (Collins 1983).

Briggs Phillips used a matched case–control study of 33 laboratory workers who experienced a laboratory associated injury over a 2-year period (Briggs Phillips, 1986). No differences were noted related to age, length of employment, years of formal education, wearing of glasses, use of prescription medications, off-the-job accidents, or driving record. On the other hand, accident-involved people were significantly more likely to have had a laboratory accident or laboratory infection prior to the 2-year study period and were significantly more likely to have a low opinion of laboratory safety programs. When the conditions surrounding the accidents were examined, 36 percent occurred when the employee was working too quickly, either just before lunch or at the end of the day. In 30 percent of accidents, the employee acknowledged a breech in safety regulations. In summary, in this study, attitudes and work habits were important contributing factors to laboratory accidents. Of note, to date there have been no published studies that confirm or refute these findings.

Quality assurance materials

Clinical laboratory workers are aware of the risks and hazards associated with handling clinical samples; however, laboratory-acquired infections in clinical laboratories can occur from improper handling not only of clinical samples but also of quality control materials, especially proficiency testing samples. In 1980, Blaser and Feldman (1980) reported 24 cases of infection with *Salmonella typhi* resulting from national proficiency testing program samples. A similar experience was repeated by Chin (1988) with an infection in a worker with *Corynebacterium diphtheriae*. In 2002, Richardson et al. (2002) reported two workers in separate laboratories infected with *Shigella flexneri* from external quality assessment samples that clinically simulated fecal samples. All materials within a laboratory, regardless of source, must be handled with all required safety and diligence.

BIOSAFETY QUALITY MANAGEMENT

Risk assessment

Laboratory biosafety programs may be driven by the recognition of good practices, in some jurisdictions may be directed by the application of established international standards, and in others may be driven by regulatory requirements. All laboratorians should regularly survey the facilities for potential hazards and implement corrective plans. Assessments should be formal, systematic, and planned, and cover all laboratory elements, including safety manual policies and procedures, training requirements and performance,

supervision, maintenance of hazardous materials and substances, first aid services and equipment, personnel safety, and health reports (ISO 2002).

Laboratory safety officer

All laboratories should designate a knowledgeable, trained, and experienced individual with the responsibility of ensuring laboratory safety. The position may require only part-time activity or may be a full-time responsibility. The responsibilities and authorities of the safety officer vis-à-vis the laboratory workers and management, and their role with respect to reporting and ability to initiate action, should be clearly defined. The laboratory safety officer should execute their activities on behalf of the laboratory management and at the same time have both the authority and responsibility to act independently and effectively. The roles of a laboratory safety officer may vary depending on the size and complexity of the facility; however, as a minimum, they should include (WHO 2003a):

- establishing and monitoring a laboratory safety program to a process of regular audit;
- performance of regular risk assessment, and development of recommendations for laboratory safety improvement;
- participating in investigation of accidental exposures, in order to prevent their occurrence;
- identifying the training needs of laboratory workers, and assisting with training implementation;
- ensuring that laboratory procedures for decontamination and disinfection are followed.

CLASSIFICATION SYSTEMS TO CLARIFY RISK

Three commonly recognized classification schemes are integral to defining the degree of risk associated with the handling of infectious materials and agents. The first is the classification of organisms, the second is the classification of environments, and the third is the classification of behaviors.

Classification of organisms

Given the variety of experiences and possible exposures, it is accepted that some microorganisms are more pathogenic than others. This may in part be due to the broad range of virulence factors that affect attachment, invasions, tissue tropisms, and production of exotoxins. While laboratorians need to have cautionary respect for everything they handle, it is accepted that some are inherently more dangerous and need to be addressed with an increased level of safety procedures and concern.

In order to designate increasing risk, national bodies including the Health Canada Bureau of Biosafety, Centers for Disease Control, National Institutes of Health, European Union, and Australia (ABSA 1998), have developed and harmonized a classification system for microorganisms that is subclassified across the spectrum of virulence. Classifications of microorganisms have traditionally been based on four stages:

Category 1: Microbes not known to consistently cause disease in healthy adults. Examples of category 1 organisms include *Bacillus subtilis* and *Naeglaria gruberi*. Microorganisms assigned to category 1 can be safely addressed in all categories of laboratories.
Category 2: Microbes that may commonly cause disease as a consequence of injury or ingestion. Therapy is readily available. Organisms tend not to spread or represent a significant community concern. Examples of category 2 organisms include *Staphylococcus* spp, most *Enterobacteriaceae*, pseudomonads, and hepatitis B virus.
Category 3: Microbes that have the potential for aerosol transmission. Therapy may be less readily available. May be indigenous or exotic agents. Examples of category 3 organisms include *Mycobacterium tuberculosis* and *Brucella* spp.
Category 4: Microbes that are exotic and dangerous, and that pose a high risk of life-threatening disease. May be transmitted by aerosol spread. Examples of category 4 agents include tick-borne encephalitis virus, Marburg virus, and Ebola fever virus.

While the classification of most agents is relatively straightforward, some organisms, such as rabies virus, dengue virus, and *Bacillus anthracis*, may be classified differently by different agencies. In these situations, appropriate handling of these agents depends on the circumstances, the availability of settings, and, above all, the practice behaviors. Note that complete listings of organisms can be obtained through examination of the tables drafted for the original documents

Classification of laboratory environments

Having established a microbial risk-classification system, it is appropriate to develop parallel and coordinated systems for addressing the handling of microorganisms safely. All laboratory workers require a safe working environment; however, it is critical that the intensity of the safety is seen to be appropriate to the inherent level of risk to avoid on the one hand undue potential of exposure to dangerous organisms and on the other hand unreasonable interference in work practices when handling commonplace pathogens. Classification of laboratory environments is relatively straightforward in research and reference laboratories where the workload and pathogen awareness are predictable. Specific requirements are more problematic in the clinical

laboratory setting because of the potential for a broad range of samples and microorganisms; that being said, even in this setting, there exists a high probability that most microorganisms processed are of category 2. While infrequent, clinical laboratories do receive risk group 3 pathogens, including *Mycobacterium tuberculosis* and *Francesella tulerensis*, and need to be prepared for the possibility.

Clinical and research laboratories can also be distinguished based on the types of organisms likely to be handled or processed. Biosafety level (BSL) 1 requirements are the most basic and general and are required for all laboratories. Each subsequent BSL builds upon the level below. BSL 4 provides the highest level of sophistication and safety.

BSL 1 facilities should be separated from public access by a lockable door. A biohazard sign should be posted at the entrance. There should be handwashing sinks readily available. Work surfaces should be constructed of materials that allow for proper disinfection. There should be equipment available for the safe decontamination of wastes prior to disposal. Special containment equipment need not be available; however, mechanical pipetting devices are mandatory for all pipetting procedures. Personal protective equipment, including laboratory gowns, coats, gloves, and eyewear, are required to be available for appropriate use. Laboratories designated as BSL 1 would be appropriate for undergraduate or secondary education and training but would be inappropriate for work involving samples of human blood or other tissues or body fluids.

BSL 2 facilities need to adhere to the requirements as above. In addition, door signage should include the name and contact information of the primary responsible person. Biological safety cabinets and other containment equipments are recommended to be available if procedures involving large inocula are to be performed, and emergency eyewash equipment should be available. While regional regulations would vary, most clinical microbiology laboratories would be required to meet the requirements of BSL 2 facilities.

BSL 3 facilities are designed to a higher level of security. A higher degree of door security is required, often under key, key card, or electronic access. BSL 3 laboratories are maintained under negative pressure, and access to the laboratories is through a vestibule or anteroom in order to protect the integrity of the pressure gradient. Exhaust air pressure handling systems is monitored and controlled. All interior surfaces, including walls, floors, and ceilings, need to be impact-resistant and without separations that would allow microorganisms to reside. Office areas are not allowed within BSL 3 facilities.

BSL 4 facilities are designed for the handling of dangerous and exotic organisms. Often, BSL 4 facilities are in separate buildings built to the required specification. In addition to the BSL 3 requirements, access to the laboratory must be through an anteroom with interlocking airtight doors. The anteroom area provides space for changing containment suits and for both chemical and water showers. Air supply into the laboratory is filtered with high-efficiency particulate air (HEPA). Outbound air passes through a two-stage HEPA filter process. Autoclaves need to be of a double-door design with interlocking doors to prevent accidental release of waste. All plumbing drains must pass through an effluent sterilization system.

Classification of laboratory practices

Just as handling of organisms and materials with increasing levels of risk requires increased levels of laboratory security, the practices of laboratorians can be scaled to risk.

General practices for all laboratory practice requires that all personnel working within a facility are trained and knowledgeable of the potential hazards to which they may be exposed, at least to the level of their competence and expertise. Eating and drinking and similar practices are not allowed within the laboratory workspace. The laboratory environment should be maintained tidily. Oral pipetting is prohibited. Long hair should be tied back or otherwise restrained. Protective garb and equipment should be available and be worn and used properly. Use of sharps should be strictly limited. All injuries should be reported without delay. All equipment, and especially autoclaves, should be maintained in good working order in order to prevent leaks, spills, and release of viable organisms. There should be an up-to-date laboratory safety manual that is available to all. The manual should include information on hazards within the specific laboratory, required safety information including material safety data sheets, and policies and procedures for all safety practices. Handwashing should be a mandatory practice when hands are either known or suspected to be contaminated and when gloves are removed.

In addition, level 2 practices would ensure that entry to the laboratory is restricted to only those on official business and that hazard warning signs are clearly posted at all entry locations. A health and medical surveillance program should be provided for all those working in the facility. An emergency procedure for spills and accidents should be written and accessible.

Level 3 practices would ensure that, in addition, there is a designated biosafety officer with the appropriate authority to oversee practices, and that all persons have successfully completed training courses in the specific requirements for added precaution. All employees should not only follow required procedures but also certify in writing that they understand the protocols. Personnel need to understand that when performing level 3 practices, the laboratory should be locked and

they must stay within the laboratory in order to maintain traffic at a minimum. Personal items are not brought into the laboratory. Personal clothing and jewelry should not be worn while performing level 3 practices. Laboratory-specific protective equipment and footwear should not be worn outside the laboratory.

In most situations and most facilities, practices and facilities would be in sync with the most common agents that pass through the facility. On some occasions, where a heightened level of concern exists, the level of recommended practices would raise. A case in point are the recommendations for laboratories likely to receive and process samples from patients with severe acute respiratory syndrome (SARS) containing coronavirus SARS-CoV. This agent, first recognized in the spring of 2003, was noted to transmit by both aerosols and contact and was often associated with a severe atypical pneumonia. While routine handling of diagnostic samples for serology or bacteriology and mycology agents was acceptable, it was deemed appropriate to recommend that workers performing procedures likely to result in aerosols follow practices more consistent with level 3, which included wearing disposable gloves, a mask or respirator, and eye protection, or a full-face shield (WHO 2003b). Despite this, there have been laboratory-acquired infections recorded while working with live strains of SARS-CoV in level 3 facilities.

At the highest level of security, level 4 practices entail all the aforementioned, but also require establishment of protocols to cover emergencies to cover possible damage to positive pressure suits. Staff should be highly trained and knowledgeable about all entry and exit procedures. They should be knowledgeable and experienced in working with all small and large animals, as may be required. They must keep a detailed log book of all agents handled, including date and time and procedures performed. A daily log should be maintained for all workers to monitor and report any and all illnesses (Health Canada 1996).

PREVENTION OF INFECTIONS

Biosafety measures to prevent laboratory-acquired infections are a combination of ready awareness, application of knowledge and education, proper use of personal protective equipment, devices, and procedures, and application of specific public-health measures. Breakdown in any domain can result in significant injury and illness.

Respiratory protective devices

Arguably, the most dangerously formed structure in the laboratory is the microbially contaminated airborne aerosol of respirable size. Microbially contaminated droplets larger than 5 μm settle rapidly, and while they tend not to be inhaled, they may be associated with contamination of the environment. Droplets smaller than 1–5 μm remain suspend in air longer and are more likely associated with inhalation (Hatch 1961).

Individual procedures tend to be associated with aerosols of certain size. Protection from droplets may be addressed by a variety of equipments. Large liquid splatters may be contained by splash guards or face masks. Smaller aerosols are far better contained by a properly functioning biological safety cabinet. The decision with respect to the most appropriate equipment would need to take into consideration the procedure being performed, potential agents, possible concentration, and availability of equipment.

Masks that are properly worn, covering the nose and mouth, provide the most direct respiratory protection. Disposable masks are constructed of a variety of materials and styles, either molded or pleated. Additional changes may include the application of hydrophobic coating to make the mask more water-resistant or the application of a face mask to provide eye protection. Application of masks may be by ear-loops, tie-on straps, or snug elastic bands.
